ANATOMY,

DESCRIPTIVE AND SURGICAL.

BY

HENRY GRAY, F.R.S.,

FELLOW OF THE ROYAL COLLEGE OF SURGEONS; LECTURER ON ANATOMY AT ST. GEORGE'S
HOSPITAL MEDICAL SCHOOL.

EDITED BY

T. PICKERING PICK, F.R.C.S.,

CONSULTING SURGEON TO ST. GEORGE'S HOSPITAL AND TO THE VICTORIA HOSPITAL FOR CHILDREN;
H. M. INSPECTOR OF ANATOMY IN ENGLAND AND WALES,

AND

ROBERT HOWDEN, M.A., M.B., C.M.,

PROFESSOR OF ANATOMY IN THE UNIVERSITY OF DURHAM; EXAMINER IN ANATOMY IN
THE UNIVERSITIES OF DURHAM AND EDINBURGH. AND TO THE
BOARD OF EDUCATION, SOUTH KENSINGTON.

with a new Introduction by
JOHN A. CROCCO, M.D.

CHIEF OF PULMONARY SERVICES, ST. VINCENT'S HOSPITAL
AND MEDICAL CENTER OF NEW YORK,
AND ASSISTANT PROFESSOR OF CLINICAL MEDICINE,
NEW YORK UNIVERSITY SCHOOL OF MEDICINE

A REVISED AMERICAN. FROM THE FIFTEENTH ENGLISH, EDITION.

WITH 780 ILLUSTRATIONS, MANY OF WHICH ARE NEW.

Introduction

Anatomy is the gateway to medicine. It is the queen of the basic sciences and is the *sine qua non* for entry into the field of human biology. It is one of the first courses taught in medical school, and in those medical schools where it was experimentally placed later in the curriculum the continuity of medical education suffered because the horse followed, rather than preceded, the cart. To study other basic sciences or clinical medicine before anatomy proved to be unrealistic, and to study medicine without anatomy was folly.

Every living physician today has been exposed to *Gray's Anatomy* and nearly every one has used it. In the stack of books carried home from the medical bookstore that first day of medical school it was the largest and often the heaviest. It was *Gray's Anatomy* that occupied most of the embryonic physician's waking hours, whether at home, or at the side of his cadaver.

There have been many imitations, but few real competitors. Anatomical narratives have been written to take the hand of the physician and guide it through the dissection of a cadaver. There have been dissection manuals and pictorial atlases brilliantly illustrated with exquisite photographs. There have been synopses of anatomy and there have been monographs on various regions of the body. However, there is only one *Gray's Anatomy*.

This stellar book represents the acme of anatomical description over the last century and will probably still be the premier text in anatomy over the next one hundred years. When anatomical dilemmas or refined questions related to gross anatomy require a definitive answer, *Gray's* is the book all students turn to. It is the *Summa* in its field.

This commemorative edition is a very fitting tribute to Dr. Henry Gray, Fellow of the Royal College of Surgeons, whose colossal work will be remembered by medical historians past and future and by twentieth-century physicians and surgeons as the anatomy text of our age.

John A. Crocco, M.D.

Chief of Pulmonary Services,
St. Vincent's Hospital and Medical
Center of New York, and Assistant
Professor of Clinical Medicine,
New York University School of Medicine
March, 1977

PUBLISHERS' NOTE TO THE NEW AMERICAN EDITION.

IN his masterpiece HENRY GRAY left undying evidence of his anatomical knowledge and of his comprehension of the best method of imparting it to other minds. It is appropriate that a new and thoroughly revised edition of such a work should appear in the opening of the new century—for forty-five years it has easily held the front place among works on Anatomy, and its merits are only brightened by the numerous works which have endeavored to contest its supremacy. During that time it has had the benefit of the careful scrutiny of many leading anatomists of the English-speaking race. Anatomy is far from stationary, either in its facts or in improvements in the method of their presentation; hence any work which would faithfully reflect the existing position of the science must be revised at comparatively frequent intervals. Fortunately for students and practitioners, *Gray's Anatomy* enjoys a continuous demand rendering frequent revision possible.

The splendid illustrations in *Gray* have long been known as the most effective and intelligible presentations of anatomical structures ever produced. In the present revision this series has been vastly improved, special attention having been given to those for the portion on General Anatomy and Embryology.

The practical application of anatomical facts in medicine and surgery has always been a prominent feature of the work, and this distinctive characteristic has received especial care.

This *new century* edition is presented to the medical public with the absolute confidence that it will be found worthy in every respect to maintain the exalted position which the work has for so many years enjoyed as the most convenient and intelligible exposition of its subject.

CONTENTS.

DESCRIPTIVE AND SURGICAL ANATOMY.

OSTEOLOGY—THE SKELETON.

INDEX	1217
-----------------	------

DESCRIPTIVE AND SURGICAL ANATOMY

OSTEOLOGY—THE SKELETON.

THE entire skeleton in the adult consists of 200 distinct bones. These are—

The spine or vertebral column (sacrum and coccyx included)	26
Cranium	8
Face	14
Hyoid bone, sternum, and ribs	26
Upper extremities	64
Lower extremities	62
	<hr/> 200

In this enumeration the patellæ are included as separate bones, but the smaller sesamoid bones and the ossicula auditûs are not reckoned. The teeth belong to the tegumentary system.

These bones are divisible into four classes: *Long*, *Short*, *Flat*, and *Irregular*.

The **Long Bones** are found in the limbs, where they form a system of levers, which have to sustain the weight of the trunk and to confer the power of locomotion. A long bone consists of a shaft and two extremities. The *shaft* is a hollow cylinder, contracted and narrowed to afford greater space for the bellies of the muscles; the walls consist of dense, compact tissue of great thickness in the middle, but becoming thinner toward the extremities; the spongy tissue is scanty, and the bone is hollowed out in its interior to form the *medullary canal*. The *extremities* are generally somewhat expanded for greater convenience of mutual connection, for the purposes of articulation, and to afford a broad surface for muscular attachment. Here the bone is made up of spongy tissue with only a thin coating of compact substance. The long bones are not straight, but curved, the curve generally taking place in two directions, thus affording greater strength to the bone. The bones belonging to this class are the *clavicle*, *humerus*, *radius*, *ulna*, *femur*, *tibia*, *fibula*, *metacarpal* and *metatarsal* bones, and the *phalanges*.

Short Bones.—Where a part of the skeleton is intended for strength and compactness, and its motion is at the same time slight and limited, it is divided into a number of small pieces united together by ligaments, and the separate bones are short and compressed, such as the bones of the *carpus* and *tarsus*. These bones, in their structure, are spongy throughout, excepting at their surface, where there is a thin crust of compact substance. The *patellæ* also, together with the other sesamoid bones, are by some regarded as short bones.

Flat Bones.—Where the principal requirement is either extensive protection or the provision of broad surfaces for muscular attachment, we find the osseous structure expanded into broad, flat plates, as is seen in the bones of the skull and the shoulder-blade. These bones are composed of two thin layers of compact tissue enclosing between them a variable quantity of cancellous tissue. In the cranial bones these layers of compact tissue are familiarly known as the *tables* of the

skull; the outer one is thick and tough; the inner one thinner, denser, and more brittle, and hence termed the *vitreous table*. The intervening cancellous tissue is called the *diploë*. The flat bones are: the *occipital*, *parietal*, *frontal*, *nasal*, *lachrymal*, *vomer*, *scapula*, *os inhommatum*, *sternum*, *ribs*, and *patella*.

The **Irregular or Mixed Bones** are such as, from their peculiar form, cannot be grouped under either of the preceding heads. Their structure is similar to that of other bones, consisting of a layer of compact tissue externally, and of spongy cancellous tissue within. The irregular bones are: the *vertebræ*, *sacrum*, *coccyx*, *temporal*, *sphenoid*, *ethmoid*, *malar*, *superior maxillary*, *inferior maxillary*, *palate*, *inferior turbinated*, and *hyoid*.

Surfaces of Bones.—If the surface of any bone is examined, certain eminences and depressions are seen to which descriptive anatomists have given the following names.

These eminences and depressions are of two kinds: *articular* and *non-articular*. Well-marked examples of articular eminences are found in the heads of the humerus and femur and of articular depressions in the glenoid cavity of the scapula and the acetabulum. Non-articular eminences are designated according to their form. Thus, a broad, rough, uneven elevation is called a *tuberosity*; a small, rough prominence, a *tubercle*; a sharp, slender, pointed eminence, a *spine*; a narrow, rough elevation, running some way along the surface, a *ridge* or *line*.

The non-articular depressions are also of very variable form, and are described as *fossæ*, *grooves*, *furrows*, *fissures*, *notches*, etc. These non-articular eminences and depressions serve to increase the extent of surface for the attachment of ligaments and muscles, and are usually well marked in proportion to the muscularity of the subject.

A prominent process projecting from the surface of a bone, which it has never been separate from or movable upon is termed an *apophysis* (from ἀπόφυσις, an excrescence); but if such process is developed as a separate piece from the rest of the bone, to which it is afterward joined, it is termed an *epiphysis* (from ἐπίφυσις, an accretion). The main part of the bone, or shaft, which is formed from the primary centre of ossification, is termed the *diaphysis*, and is separated, during growth, from the epiphysis by a layer of cartilage, at which growth in length of the bone takes place.

THE SPINE.

The **Spine** is a flexuous and flexible column formed of a series of bones called *vertebræ* (from *vertere*, to turn).

The **Vertebræ** are thirty-three in number, and have received the names *cervical*, *dorsal*, *lumbar*, *sacral*, and *coccygeal*, according to the position which they occupy; seven being found in the cervical region, twelve in the dorsal, five in the lumbar, five in the sacral, and four in the coccygeal.

This number is sometimes increased by an additional vertebra in one region, or the number may be diminished in one region, the deficiency being supplied by an additional vertebra in another. These observations do not apply to the cervical portion of the spine, the number of bones forming which is seldom increased or diminished.

The *vertebræ* in the upper three regions of the spine are separate throughout the whole of life; but those found in the sacral and coccygeal regions are in the adult firmly united, so as to form two bones—*five* entering into the formation of the upper bone or *sacrum*, and *four* into the terminal bone of the spine or *coccyx*.

General Characters of a Vertebra.

Each **vertebra** consists of two essential parts—an anterior solid segment or *body*, and a posterior segment or *arch*. The arch (*neural*) is formed of two *pedicles* and two *laminae*, supporting seven *processes*—viz. four *articular*, two *transverse*, and one *spinous*.

The bodies of the *vertebræ* are piled one upon the other, forming a strong

pillar for the support of the cranium and trunk; the arches forming a hollow cylinder behind the bodies for the protection of the spinal cord. The different vertebræ are connected together by means of the articular processes and the intervertebral fibro-cartilages; while the transverse and spinous processes serve as levers for the attachment of muscles which move the different parts of the spine. Lastly, between each pair of vertebræ apertures exist through which the spinal nerves pass from the cord. Each of these constituent parts must now be separately examined.

The **Body or Centrum** is the largest part of a vertebra. Above and below, it is flattened; its upper and lower surfaces are rough for the attachment of the intervertebral fibro-cartilages, and present a rim around their circumference. In front, it is convex from side to side, concave from above downward. Behind, it is flat from above downward and slightly concave from side to side. Its anterior surface is perforated by a few small apertures, for the passage of nutrient vessels; whilst on the posterior surface is a single large, irregular aperture, or occasionally more than one, for the exit of veins from the body of the vertebra—the *venæ basis vertebræ*.

The **Pedicles** are two short, thick pieces of bone, which project backward, one on each side, from the upper part of the body of the vertebra, at the line of junction of its posterior and lateral surfaces. The concavities above and below the pedicles are the *intervertebral notches*; they are four in number, two on each side, the inferior ones being generally the deeper. When the vertebræ are articulated the notches of each contiguous pair of bones form the intervertebral foramina, which communicate with the spinal canal and transmit the spinal nerves and blood-vessels.

The **Laminæ** are two broad plates of bone which complete the neural arch by fusing together in the middle line behind. They enclose a foramen, the *spinal foramen*, which serves for the protection of the spinal cord; they are connected to the body by means of the pedicles. Their upper and lower borders are rough, for the attachment of the *ligamenta subflava*.

The **Spinous Process** projects backward from the junction of the two laminæ, and serves for the attachment of muscles and ligaments.

The **Articular Processes**, four in number, two on each side, spring from the junction of the pedicles with the laminæ. The two superior project upward, their articular surfaces being directed more or less backward; the two inferior project downward, their articular surfaces looking more or less forward.¹

The **Transverse Processes**, two in number, project one at each side from the point where the lamina joins the pedicle, between the superior and inferior articular processes. They also serve for the attachment of muscles and ligaments.

Character of the Cervical Vertebrae (Fig. 1).

The **Cervical Vertebrae** are smaller than those in any other region of the spine, and may readily be distinguished by the foramen in the transverse process, which does not exist in the transverse process of either the dorsal or lumbar vertebrae.

The **Body** is small, comparatively dense, and broader from side to side than from before backward. The anterior and posterior surfaces are flattened and of equal depth; the former is placed on a lower level than the latter, and its inferior border is prolonged downward, so as to overlap the upper and fore part of the vertebra below. Its upper surface is concave transversely, and presents a projecting lip on each side; its lower surface is convex from side to side, concave from before backward, and presents laterally a shallow concavity which receives the corresponding projecting lip of the adjacent vertebra. The *pedicles* are directed outward and backward, and are attached to the body midway between the upper and lower borders, so that the superior intervertebral notch is as deep as the inferior, but it is, at the same time, narrower. The *laminæ* are narrow,

¹ It may, perhaps, be as well to remind the reader that the direction of a surface is determined by that of a line drawn at right angles to it.

long, thinner above than below, and overlap each other, enclosing the spinal foramen, which is very large, and of a triangular form. The *spinous process* is short, and bifid at the extremity to afford greater extent of surface for the attachment of muscles, the two divisions being often of unequal size. They increase in length from the fourth to the seventh. The *articular processes* are flat, oblique, and of an oval form: the superior are directed backward and upward; the inferior forward and downward. The *transverse processes* are short, directed downward, outward, and forward, bifid at their extremity, and marked by a groove along their upper surface, which runs downward and outward from the superior intervertebral notch, and serves for the transmission of one of the cervical nerves. They are situated in front of the articular processes and on the outer side of the pedicles. The transverse processes are pierced at their base by a foramen, for the transmission of the vertebral artery, vein, and plexus of nerves.

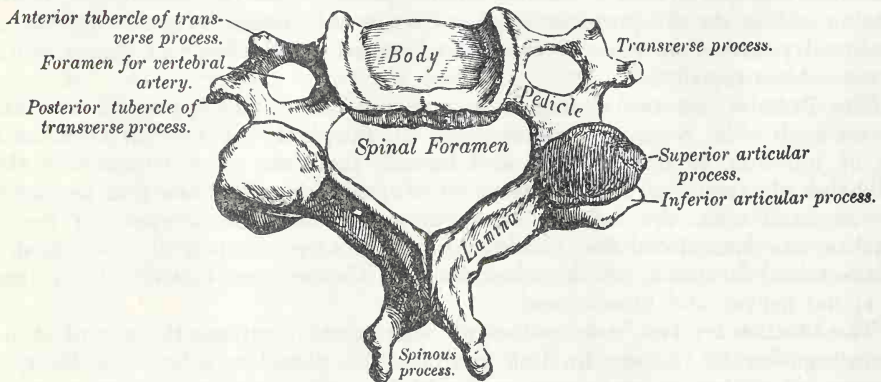

FIG. 1.—Cervical vertebra.

Each process is formed by two roots: the anterior root, sometimes called the *costal process*, arises from the side of the body, and is the homologue of the rib in the dorsal region of the spine; the posterior root springs from the junction of the pedicle with the lamina, and corresponds with the transverse process in the dorsal region. It is by the junction of the two that the foramen for the vertebral vessels is formed. The extremity of each of these roots forms the *anterior* and *posterior tubercles* of the transverse processes.¹

The peculiar vertebrae in the cervical region are the first, or *Atlas*; the second, or *Axis*; and the seventh, or *Vertebra prominens*. The great modifications in the form of the atlas and axis are designed to admit of the nodding and rotatory movements of the head.

The *Atlas* (Fig. 2) is so named from supporting the globe of the head. The chief peculiarities of this bone are that it has neither body nor spinous process. The body is detached from the rest of the bone, and forms the odontoid process of the second vertebra; while the parts corresponding to the pedicles join in front to form the anterior arch. The atlas is ring-like, and consists of an anterior arch, a posterior arch, and two lateral masses. The *anterior arch* forms about one-fifth of the ring: its anterior surface is convex, and presents about its centre a *tubercle*, for the attachment of the Longus colli muscle; posteriorly it is concave, and marked by a smooth, oval or circular facet, for articulation with the odontoid process of the axis. The upper and lower borders give attachment to the anterior occipito-atlantal and the anterior atlanto-axial ligaments, which connect it with the occipital bone above and the axis below. The *posterior arch* forms about two-fifths of the circumference of the bone; it terminates behind in a *tubercle*,

¹ The anterior tubercle of the transverse process of the sixth cervical vertebra is of large size, and is sometimes known as "Chassaignac's" or the "carotid tubercle." It is in close relation with the carotid artery, which lies in front and a little external to it so that, as was first pointed out by Chassaignac, the vessel can with ease be compressed against it.

which is the rudiment of a spinous process, and gives origin to the Rectus capitis posticus minor. The diminutive size of this process prevents any interference in the movements between the atlas and the cranium. The posterior part of the arch presents above and behind a rounded edge for the attachment of the posterior occipito-atlantal ligament, while in front, immediately behind each superior articular process, is a groove, sometimes converted into a foramen by a *delicate bony spiculum* which arches backward from the posterior extremity of the superior articular process. These grooves represent the superior intervertebral notches, and are peculiar from being situated behind the articular processes, instead of in front of them, as in the other vertebræ. They serve for the transmission of the vertebral artery, which, ascending through the foramen in the transverse process, winds round the lateral mass in a direction backward and inward. They also transmit the suboccipital (first spinal) nerve. On the under surface of the posterior arch, in the same situation, are two other grooves, placed behind the lateral masses, and representing the inferior intervertebral notches of other vertebræ. They are much less marked than the superior. The lower border also gives attachment to the posterior atlanto-axial ligament, which connects it with the axis. The *lateral masses* are the most bulky and solid parts of the atlas, in order to support the weight of the head; they present two articulating processes above, and two below. The two superior are of large size, oval,

FIG. 2. — First cervical vertebra, or atlas.

concave, and approach each other in front, but diverge behind; they are directed upward, inward, and a little backward, each forming a kind of cup for the corresponding condyle of the occipital bone, and are admirably adapted to the nodding movements of the head. Not infrequently they are partially subdivided by a more or less deep indentation which encroaches upon each lateral margin. The inferior articular processes are circular in form, flattened or slightly concave, and directed downward and inward, articulating with the axis, and permitting the rotatory movements. Just below the inner margin of each superior articular surface is a small tubercle, for the attachment of the transverse ligament, which, stretching across the ring of the atlas, divides it into two unequal parts; the anterior or smaller segment receiving the odontoid process of the axis, the posterior allowing the transmission of the spinal cord and its membranes. This part of the spinal canal is of considerable size, to afford space for the spinal cord; and hence lateral displacement of the atlas may occur without compression of this structure. The *transverse processes* are of large size, project directly outward and downward from the lateral masses, and serve for the attachment of special muscles which assist in rotating the head. They are long, not bifid, and perforated at their base by a canal for the vertebral artery, which is directed from below, upward and backward.

The *Axis* (Fig. 3) is so named from forming the pivot upon which the first vertebra, carrying the head, rotates. The most distinctive character of this bone

is the strong, prominent process, tooth-like in form (hence the name *odontoid*), which rises perpendicularly from the upper surface of the body. The *body* is deeper in front than behind, and prolonged downward anteriorly so as to overlap the upper and fore part of the next vertebra. It presents in front a median

FIG. 3.—Second cervical vertebra, or axis.

longitudinal ridge, separating two lateral depressions for the attachment of the Longus colli muscle of either side. The *odontoid process* presents two articulating surfaces: one in front, of an oval form, for articulation with the atlas; another behind, for the transverse ligament—the latter frequently encroaching on the sides of the process. The apex is pointed, and gives attachment to the middle fasciculus of the odontoid or check ligaments (*ligamentum suspensorium*). Below the apex the process is somewhat enlarged, and presents on either side a rough impression for the attachment of the *lateral fasciculi* of the odontoid or *check ligaments*, which connect it to the occipital bone; the base of the process, where it is attached to the body, is constricted, so as to prevent displacement from the

FIG. 4.—Seventh cervical vertebra, or vertebra prominens.

transverse ligament, which binds it in this situation to the anterior arch of the atlas. Sometimes, however, this process does become displaced, especially in children, in whom the ligaments are more relaxed: instant death is the result of this accident. The internal structure of the odontoid process is more compact than that of the body. The *pedicles* are broad and strong, especially their anterior extremities, which coalesce with the sides of the body and the root of the odontoid process. The *laminae* are thick and strong, and the spinal foramen large, but smaller than that of the atlas. The *transverse processes* are very small, not bifid, and perforated by the foramen for the vertebral artery, which is

directed obliquely upward and outward. The *superior articular surfaces* are round, slightly convex, directed upward and outward, and are peculiar in being supported on the body, pedicles, and transverse processes. The *inferior articular surfaces* have the same direction as those of the other cervical vertebrae. The *superior*

intervertebral notches are very shallow, and lie behind the articular processes; the *inferior* in front of them, as in the other cervical vertebræ. The *spinous process* is of large size, very strong, deeply channelled on its under surface, and presents a bifid, tubercular extremity for the attachment of muscles which serve to rotate the head upon the spine.

Seventh Cervical (Fig. 4).—The most distinctive character of this vertebra is the existence of a very long and prominent spinous process; hence the name “vertebra prominens.” This process is thick, nearly horizontal in direction, not bifurcated, and has attached to it the lower end of the ligamentum nuchæ. The *transverse process* is usually of large size, its posterior tubercles are large and prominent, while the anterior are small and faintly marked; its upper surface has usually a shallow groove, and it seldom presents more than a trace of bifurcation at its extremity. The foramen in the transverse process is sometimes as large as in the other cervical vertebræ, but is usually smaller on one or both sides, and sometimes wanting. On the left side it occasionally gives passage to the vertebral artery; more frequently the vertebral vein traverses it on both sides; but the usual arrangement is for both artery and vein to pass in front of the transverse process, and not through the foramen. Occasionally the anterior root of the transverse process exists as a separate bone, and attains a large size. It is then known as a “cervical rib.”

Characters of the Dorsal Vertebræ.

The **Dorsal Vertebræ** are intermediate in size between those in the cervical and those in the lumbar region, and increase in size from above downward, the upper

FIG. 5.—A dorsal vertebra.

vertebræ in this segment of the spine being much smaller than those in the lower part of the region. The dorsal vertebræ may be at once recognized by the presence on the sides of the body of one or more facets or half-facets for the heads of the ribs.

The **bodies** of the dorsal vertebræ resemble those in the cervical and lumbar regions at the respective ends of this portion of the spine; but in the middle of the dorsal region their form is very characteristic, being heart-shaped, and as broad in the antero-posterior as in the lateral direction. They are thicker behind than in front, flat above and below, convex and prominent in front, deeply concave behind, slightly constricted in front and at the sides, and marked on each side,

near the root of the pedicle, by two demi-facets, one above, the other below. These are covered with cartilage in the recent state, and, when articulated with the adjoining vertebræ, form, with the intervening fibro-cartilage, oval surfaces for the reception of the heads of the corresponding ribs. The *pedicles* are directed backward, and the inferior intervertebral notches are of large size, and deeper than in any other region of the spine. The *laminæ* are broad, thick, and imbricated—that is to say, overlapping one another like tiles on a roof. The spinal foramen is

FIG. 6.—Peculiar dorsal vertebræ.

small, and of a circular form. The *spinous processes* are long, triangular on transverse section, directed obliquely downward, and terminate in a tubercular extremity. They overlap one another from the fifth to the eighth, but are less oblique in direction above and below. The *articular processes* are flat, nearly vertical in direction, and project from the upper and lower part of the pedicles; the superior being directed backward and *slightly* outward and upward, the inferior

forward and a little inward and downward. The *transverse processes* arise from the same parts of the arch as the posterior roots of the transverse processes in the neck, and are situated behind the articular processes and pedicles; they are thick, strong, and of great length, directed obliquely backward and outward, presenting a clubbed extremity, which is tipped on its anterior part by a small concave surface, for articulation with the tubercle of a rib. Besides the articular facet for the rib, *three indistinct tubercles* may be seen rising from the transverse processes, one at the upper border, one at the lower border, and one externally. In man they are comparatively of small size, and serve only for the attachment of muscles. But in some animals they attain considerable magnitude, either for the purpose of more closely connecting the segments of this portion of the spine or for muscular and ligamentous attachment.

The peculiar dorsal vertebræ are the *first, ninth, tenth, eleventh, and twelfth* (Fig. 6).

The **First Dorsal Vertebra** presents, on each side of the *body*, a single entire articular facet for the head of the first rib and a half facet for the upper half of the second. The body is like that of a cervical vertebra, being broad transversely; its upper surface is concave, and lipped on each side. The *articular surfaces* are oblique, and the *spinous process* thick, long, and almost horizontal.

The **Ninth Dorsal** has no demi-facet below. In some subjects, however, the ninth has two demi-facets on each side; when this occurs the tenth has only a demi-facet at the upper part.

The **Tenth Dorsal** has (except in the cases just mentioned) an entire articular facet on each side, above, which is partly placed on the outer surface of the pedicle. It has no demi-facet below.

In the **Eleventh Dorsal** the body approaches in its form and size to the lumbar. The articular facets for the heads of the ribs, one on each side, are of large size, and placed chiefly on the pedicles, which are thicker and stronger in this and the next vertebra than in any other part of the dorsal region. The *spinous process* is short, and nearly horizontal in direction. The *transverse processes* are very short, tubercular at their extremities, and have no articular facets for the tubercles of the ribs.

The **Twelfth Dorsal** has the same general characters as the eleventh, but may be distinguished from it by the inferior articular processes being convex and turned outward, like those of the lumbar vertebræ; by the general form of the body, laminae, and spinous process, approaching to that of the lumbar vertebræ; and by the transverse processes being shorter, and marked by three elevations, the superior, inferior, and external tubercles, which correspond to the mammillary, accessory, and transverse processes of the lumbar vertebræ. Traces of similar elevations are usually to be found upon the other dorsal vertebræ (*vide ut supra*).

Characters of the Lumbar Vertebræ.

The **Lumbar Vertebræ** (Fig. 7) are the largest segments of the vertebral column, and can at once be distinguished by the absence of the foramen in the transverse process, the characteristic point of the cervical vertebræ, and by the absence of any articulating facet on the side of the body, the distinguishing mark of the dorsal vertebræ.

The *body* is large, and has a greater diameter from side to side than from before backward, slightly thicker in front than behind, flattened or slightly concave above and below, concave behind, and deeply constricted in front and at the sides, presenting prominent margins, which afford a broad basis for the support of the superincumbent weight. The *pedicles* are very strong, directed backward from the upper part of the bodies; consequently, the inferior intervertebral notches are of considerable depth. The *laminae* are broad, short, and strong, and the spinal foramen triangular, larger than in the dorsal, smaller than in the cervical, region. The *spinous processes* are thick and broad, somewhat quadrilateral, horizontal in direction, thicker below than above, and terminating by a rough, uneven border.

The *superior articular processes* are concave, and look backward and inward; the *inferior*, convex, look forward and outward; the former are separated by a much wider interval than the latter, embracing the lower articulating processes of the vertebra above. The *transverse processes* are long, slender, directed trans-

FIG. 7.—Lumbar vertebra.

versely outward in the upper three lumbar vertebræ, slanting a little upward in the lower two. They are situated in front of the articular processes, instead of behind them as in the dorsal vertebræ, and are homologous with the ribs. Of the three tubercles noticed in connection with the transverse processes of the twelfth dorsal vertebra, the *superior* ones become connected in this region with the back

FIG. 8.—Lumbar vertebræ.

part of the superior articular processes, and have received the name of *mammillary* processes; the *inferior* are represented by a small process pointing downward, situated at the back part of the base of the transverse process, and called the *accessory* processes: these are the true transverse processes, which are rudimental in this region of the spine; the *external* ones are the so-called transverse processes,

the homologue of the rib, and hence sometimes called costal processes (Fig. 8). Although in man these are comparatively small, in some animals they attain considerable size, and serve to lock the vertebræ more closely together.

The **Fifth Lumbar** vertebra is characterized by having the body much thicker in front than behind, which accords with the prominence of the sacro-vertebral articulation; by the smaller size of its spinous process; by the wide interval between the inferior articulating processes; and by the greater size and thickness of its transverse processes, which spring from the body as well as from the pedicles.

Structure of the Vertebræ.—The body is composed of light, spongy, cancellous tissue, having a thin coating of compact tissue on its external surface perforated by numerous orifices, some of large size, for the passage of vessels; its interior is traversed by one or two large canals, for the reception of veins, which converge toward a single large, irregular aperture or several small apertures at the posterior part of the body of each bone. The arch and processes projecting from it have, on the contrary, an exceedingly thick covering of compact tissue.

Development.—Each vertebra is formed of four primary centres of ossification (Fig. 9), one for each lamina and its processes, and two for the body.¹ Ossifica-

FIG. 9.—Development of a vertebra.

FIG. 10.

FIG. 11.

tion commences in the laminae about the sixth week of foetal life, in the situation where the transverse processes afterward project, the ossific granules shooting backward to the spine, forward into the pedicles, and outward into the transverse and articular processes. Ossification in the body commences in the middle of the cartilage about the eighth week by two closely approximated centres, which speedily coalesce to form one central ossific point. According to some authors, ossification commences in the laminae only in the upper vertebræ—*i. e.*, in the cervical and upper dorsal. The first ossific points in the lower vertebræ are those which are to form the body, the osseous centres for the laminae appearing at a subsequent period. At birth these three pieces are perfectly separate. During the first year the laminae become united behind, the union taking place first in the lumbar region and then extending upward through the dorsal and lower cervical regions. About the third year the body is joined to the arch on each side in such a manner that the body is formed from the three original centres of ossification, the amount contributed by the pedicles increasing in extent from below upward. Thus the bodies of the sacral vertebræ are formed almost entirely from the central nuclei; the bodies of the lumbar are formed laterally and behind by the pedicles; in the dorsal region the pedicles advance as far forward as the articular depressions for the head of the ribs, forming these cavities of reception; and in the neck the

¹ By many observers it is asserted that the bodies of the vertebra are developed from a single centre which speedily becomes bilobed, so as to give the appearance of two nuclei; but that there are two centres, at all events sometimes, is evidenced by the fact that the two halves of the body of the vertebra may remain distinct throughout life and be separated by a fissure through which a protrusion of the spinal membrane may take place, constituting an anterior spina bifida.

lateral portions of the bodies are formed entirely by the advance of the pedicles. The line along which union takes place between the body and the neural arch is named the *neuro-central suture*. Before puberty no other changes occur, excepting a gradual increase in the growth of these primary centres; the upper and under surfaces of the bodies and the ends of the transverse and spinous processes being tipped with cartilage, in which ossific granules are not as yet deposited. At sixteen years (Fig. 11) three secondary centres appear, one for the tip of each transverse process, and one for the extremity of the spinous process. In some of the lumbar vertebræ, especially the first, second, and third, a second ossifying centre appears at the base of the spinous process. At twenty-one years (Fig. 10) a thin circular epiphysial plate of bone is formed in the layer of cartilage

situated on the upper and under surfaces of the body, the former being the thicker of the two. All these become joined, and the bone is completely formed between the twenty-fifth and thirtieth year of life.

Exceptions to this mode of development occur in the first, second, and seventh cervical, and in the vertebræ of the lumbar region.

The **Atlas** (Fig. 12).—The number of centres of ossification of the atlas is very variable. It may be developed from two, three, four, or five centres. The most frequent arrangement is by three centres. Two of these are destined for the two lateral or neural masses, the ossification of which commences about the seventh week near the articular processes, and extend backward; these portions of bone are separated from one another behind, at birth, by a narrow interval filled in with cartilage. Between the third and fourth years they unite either directly or

FIG. 12.—Atlas.

FIG. 13.—Axis.

FIG. 14.—Lumbar vertebra.

Exceptional cases.

through the medium of a separate centre developed in the cartilage in the middle line. The anterior arch, at birth, is altogether cartilaginous, and in this a separate nucleus appears about the end of the first year after birth, and, extending laterally, joins the neural processes in front of the pedicles. Sometimes there are two nuclei developed in the cartilage, one on either side of the median line, which join to form a single mass. And occasionally there is no separate centre, but the anterior arch is formed by the gradual extension forward and ultimate junction of the two neural processes.

The **Axis** (Fig. 13) is developed by *seven* centres. The body and arch of this bone are formed in the same manner as the corresponding parts in the other vertebræ: one centre (or two, which speedily coalesce) for the lower part of the body, and one for each lamina. The centres for the laminae appear about the seventh or eighth week, that for the body about the fourth month. The odontoid process consists originally of an extension upward of the cartilaginous mass in which the lower part of the body is formed. At about the sixth month of foetal life two osseous nuclei make their appearance in the base of this process: they are placed laterally, and join before birth to form a conical bilobed mass deeply cleft above; the interval between the cleft and the summit of the process is formed by a wedge-shaped piece of cartilage, the base of the process being separated from the body by a cartilaginous interval, which

gradually becomes ossified at its circumference, but remains cartilaginous in its centre until advanced age.¹ Finally, as Humphry has demonstrated, the apex of the odontoid process has a separate nucleus, which appears in the second year and joins about the twelfth year. In addition to these there is a secondary centre for a thin epiphysial plate on the under surface of the body of the bone.

The Seventh Cervical.—The anterior or costal part of the transverse process of the seventh cervical is developed from a separate osseous centre at about the sixth month of foetal life, and joins the body and posterior division of the transverse process between the fifth and sixth years. Sometimes this process continues as a separate piece, and, becoming lengthened outward, constitutes what is known as a cervical rib. This separate ossific centre for the costal process has also been found in the fourth, fifth, and sixth cervical vertebræ.

The Lumbar Vertebræ (Fig. 14) have *two additional centres* (besides those peculiar to the vertebræ generally) for the mammillary tubercles, which project from the back part of the superior articular processes. The transverse process of the first lumbar is sometimes developed as a separate piece, which may remain permanently unconnected with the remaining portion of the bone, thus forming a lumbar rib—a peculiarity that is rarely met with.

Progress of Ossification in the Spine generally.—Ossification of the laminæ of the vertebræ commences in the cervical region of the spine, and proceeds gradually downward. Ossification of the bodies, on the other hand, commences a little below the centre of the spinal column (about the ninth or tenth dorsal vertebra), and extends both upward and downward. Although, however, the ossific nuclei make their first appearance in the lower dorsal vertebræ, the lumbar and first sacral are those in which these nuclei are largest at birth.

Attachment of Muscles.—To the *Atlas* are attached nine pairs: the Longus colli, Rectus capitis anticus minor, Rectus lateralis, Obliquus capitis superior and inferior, Splenius colli, Levator anguli scapulæ, First Intertransverse, and Rectus capitis posticus minor.

To the *Axis* are attached eleven pairs: the Longus colli, Levator anguli scapulæ, Splenius colli, Scalenus medius, Transversalis colli, Intertransversales, Obliquus capitis inferior, Rectus capitis posticus major, Semispinalis colli, Multifidus spinæ, Interspinales.

To the remaining vertebræ, generally, are attached thirty-five pairs and a single muscle: *anteriorly*, the Rectus capitis anticus major, Longus colli, Scalenus anticus medius and posticus, Psoas magnus and parvus, Quadratus lumborum, Diaphragm, Obliquus abdominis internus, and Transversalis abdominis—*posteriorly*, the Trapezius, Latissimus dorsi, Levator anguli scapulæ, Rhomboideus major and minor, Serratus posticus superior and inferior, Splenius, Erector spinæ, Ilio-costalis, Longissimus dorsi, Spinalis dorsi, Cervicalis ascendens, Transversalis colli, Trachelo-mastoid, Complexus, Biventer cervicis, Semispinalis dorsi and colli, Multifidus spinæ, Rotatores spinæ, Interspinales, Supraspinales, Intertransversales, Levatores costarum.

Sacral and Coccygeal Vertebræ.

The **Sacral and Coccygeal Vertebræ** consist, at an early period of life, of nine separate pieces, which are united in the adult so as to form two bones, five entering into the formation of the sacrum, four into that of the coccyx. Occasionally, the coccyx consists of five bones.²

The **Sacrum** (sacer, sacred) is a large, triangular bone (Fig. 15), situated at the lower part of the vertebral column, and at the upper and back part of the pelvic cavity, where it is inserted like a wedge between the two innominate bones; its upper part or base articulating with the last lumbar vertebræ, its apex with the coccyx. The sacrum is curved upon itself, and placed very obliquely, its upper

¹ See Cunningham, *Journ. Anat.*, vol. xx. p. 238.

² Sir George Humphry describes this as the usual composition of the coccyx.—*On the Skeleton*, p. 456.

extremity projecting forward, and forming, with the last lumbar vertebra, a very prominent angle, called the *promontory* or *sacro-vertebral angle*; whilst its central part is directed backward, so as to give increased capacity to the pelvic cavity. It presents for examination an anterior and posterior surface, two lateral surfaces, a base, an apex, and a central canal.

The **Anterior Surface** is concave from above downward, and slightly so from side to side. In the middle are seen four transverse ridges, indicating the original division of the bone into five separate pieces. The portions of bone intervening between the ridges correspond to the bodies of the vertebræ. The body of the first segment is of large size, and in form resembles that of a lumbar vertebra; the succeeding ones diminish in size from above downward, are flattened from before backward, and curved so as to accommodate themselves to the form of the sacrum, being concave in front, convex behind. At each end of the ridges above mentioned are seen the *anterior sacral foramina*, analogous to the intervertebral foramina,

FIG. 15.—Sacrum, anterior surface.

four in number on each side, somewhat rounded in form, diminishing in size from above downward, and directed outward and forward; they transmit the anterior branches of the sacral nerves and the lateral sacral arteries. External to these foramina is the *lateral mass*, consisting at an early period of life of separate segments; these become blended, in the adult, with the bodies, with each other, and with the posterior transverse processes. Each lateral mass is traversed by four broad, shallow grooves, which lodge the anterior sacral nerves as they pass outward, the grooves being separated by prominent ridges of bone, which give attachment to the slips of the *Pyriformis* muscle.

If a vertical section is made through the centre of the sacrum (Fig. 16), the bodies are seen to be united at their circumference by bone, a wide interval being left centrally, which, in the recent state, is filled by intervertebral substance. In

some bones this union is more complete between the lower segments than between the upper ones.

The **Posterior Surface** (Fig. 17) is convex and much narrower than the anterior. In the middle line are three or four tubercles, which represent the rudimentary spinous processes of the sacral vertebræ. Of these tubercles, the first is usually prominent, and perfectly distinct from the rest; the second and third are either separate or united into a tubercular ridge, which diminishes in size from above downward; the fourth usually, and the fifth always, remaining undeveloped. External to the spinous processes on each side are the *laminae*, broad and well marked in the first three pieces; sometimes the fourth, and generally the fifth, are only partially developed and fail to meet in the middle line. These partially developed laminae are prolonged downward as rounded processes, the *sacral cornua*, and are connected to the cornua of the coccyx. Between them the bony wall of the lower end of the sacral canal is imperfect, and is liable to be opened in the sloughing of bed-sores. External to the laminae is a linear series of indistinct tubercles representing the *articular processes*; the upper pair are large, well developed, and correspond in shape and direction to the superior articulating processes of a lumbar vertebra; the second and third are small; the fourth and fifth (usually blended together) are situated on each side of the sacral canal and assist in forming the sacral cornua.

External to the articular processes are the four *posterior sacral foramina*; they are smaller in size and less regular in form than the anterior, and transmit the posterior branches of the sacral nerves. On the outer side of the posterior sacral foramina is a series of tubercles, the rudimentary *transverse processes* of the sacral vertebræ. The first pair of transverse tubercles are large, very distinct, and correspond with each *superior angle* of the bone; they together with the second pair, which are of small size, give attachment to the horizontal part of the sacro-iliac ligament; the third give attachment to the oblique fasciculi of the posterior sacro-iliac ligaments; and the fourth and fifth to the great sacro-sciatic ligaments. The interspace between the spinous and transverse processes on the back of the sacrum presents a wide, shallow concavity, called the *sacral groove*; it is continuous above with the vertebral groove, and lodges the origin of the Multifidus spinæ.

The **Lateral Surface**, broad above, becomes narrowed into a thin edge below. Its upper half presents in front a broad, ear-shaped surface for articulation with the ilium. This is called the *auricular surface*, and in the fresh state is coated with fibro-cartilage. It is bounded posteriorly by deep and uneven impressions, for the attachment of the posterior sacro-iliac ligaments. The lower half is thin and sharp, and terminates in a projection called the *inferior lateral angle*; below this angle is a notch, which is converted into a foramen by articulation with the transverse process of the upper piece of the coccyx, and transmits the anterior

FIG. 16.—Vertical section of the sacrum.

division of the fifth sacral nerve. This lower, sharp border gives attachment to the greater and lesser sacro-sciatic ligaments, and to some fibres of the *Gluteus maximus* posteriorly, and to the *Coccygeus* in front.

The **Base** of the sacrum, which is broad and expanded, is directed upward and forward. In the middle is seen a large oval articular surface, which is connected with the under surface of the body of the last lumbar vertebra by a fibro-cartilaginous disk. It is bounded behind by the large, triangular orifice of the sacral canal. The orifice is formed behind by the laminæ and spinous process of the first sacral vertebra: the superior articular processes project from it on each side; they are oval, concave, directed backward and inward, like the superior articular processes of a lumbar vertebra; and in front of each articular process is an intervertebral notch, which forms the lower part of the foramen between the last lumbar and first sacral vertebra. Lastly, on each side of the large oval articular

FIG. 17.—Sacrum, posterior surface.

plate is a broad and flat triangular surface of bone, which extends outward, supports the *Psoas magnus* muscle and lumbo-sacral cord, and is continuous on each side with the iliac fossa. This is called the *ala* of the sacrum, and gives attachment to a few of the fibres of the *Iliacus* muscle. The posterior part of the *ala* represents the transverse process of the first sacral segment.

The **Apex**, directed downward and slightly forward, presents a small, oval, concave surface for articulation with the coccyx.

The **Spinal Canal** runs throughout the greater part of the bone; it is large and triangular in form above, small and flattened, from before backward, below. In this situation its posterior wall is incomplete, from the non-development of the laminæ and spinous processes. It lodges the sacral nerves, and is perforated by the anterior and posterior sacral foramina, through which these pass out.

Structure.—It consists of much loose, spongy tissue within, invested externally by a thin layer of compact tissue.

Differences in the Sacrum of the Male and Female.—The sacrum in the female is shorter and wider than in the male; the lower half forms a greater angle with the upper, the upper half of the bone being nearly straight, the lower half presenting the greatest amount of curvature. The bone is also directed more obliquely backward, which increases the size of the pelvic cavity; but the sacro-vertebral angle projects less. In the male the curvature is more evenly distributed over the whole length of the bone, and is altogether greater than in the female.

Peculiarities of the Sacrum.—This bone, in some cases, consists of six pieces; occasionally, the number is reduced to four. Sometimes the bodies of the first and second segments are not joined or the laminae and spinous processes have not coalesced. Occasionally the upper pair of transverse tubercles are not joined to the rest of the bone on one or both sides; and, lastly, the sacral canal may be open for nearly the lower half of the bone, in consequence of the imperfect development of the laminae and spinous processes. The sacrum, also, varies considerably with respect to its degree of curvature. From the examination of a large number of skeletons it would appear that in one set of cases the anterior surface of this bone was nearly straight, the curvature, which was very slight, affecting only its lower end. In another set of cases the bone was curved throughout its whole length, but especially toward its middle. In a third set the degree of curvature was less marked, and affected especially the lower third of the bone.

Development (Fig. 18).—The sacrum, formed by the union of five vertebræ, has *thirty-five* centres of ossification.

The *bodies* of the sacral vertebræ have each three ossific centres: one for the central part, and one for the epiphysial plates on its upper and under surface. Occasionally the primary centres for the bodies of the first and second piece of the sacrum are double.

The arch of each sacral vertebra is developed by two centres, one for each lamina. These unite with each other behind, and subsequently join the body.

The *lateral masses* have six additional centres, two for each of the first three vertebræ. These centres make their appearance above and to the outer side of the anterior sacral foramina (Fig. 18), and are developed into separate segments

FIG. 18.—Development of the sacrum.

FIG. 19.

FIG. 20.

(Fig. 19); they are subsequently blended with each other, and with the bodies and transverse processes to form the lateral mass.

Lastly, each *lateral surface* of the sacrum is developed by two epiphysial plates (Fig. 20): one for the auricular surface, and one for the remaining part of the thin lateral edge of the bone.

Period of Development.—At about the eighth or ninth week of foetal life ossification of the central part of the bodies of the first three vertebræ commences, and at a somewhat later period that of the last two. Between the sixth and eighth months ossification of the laminae takes place; and at about the same period the centres for the lateral masses for the first three sacral vertebræ make their appearance. The period at which the arch becomes completed by the junction

of the laminae with the bodies in front and with each other behind varies in different segments. The junction between the laminae and the bodies takes place first in the lower vertebrae as early as the second year, but is not effected in the uppermost until the fifth or sixth year. About the sixteenth year the epiphyses for the upper and under surfaces of the bodies are formed, and between the eighteenth and twentieth years those for each lateral surface of the sacrum make their appearance. The bodies of the sacral vertebrae are, during early life, separated from each other by intervertebral disks. But about the eighteenth year the two lowest segments become joined together by ossification extending through the disk. This process gradually extends upward until all the segments become united, and the bone is completely formed from the twenty-fifth to the thirtieth year of life.

Articulations.—With four bones: the last lumbar vertebra, coccyx, and the two innominate bones.

Attachment of Muscles.—To eight pairs: in front, the Piriformis and Coccygeus, and a portion of the Iliacus to the base of the bone; behind, the Gluteus maximus, Latissimus dorsi, Multifidus spinæ, and Erector spinæ, and sometimes the Extensor coccygis.

The Coccyx.

The **Coccyx** (κόκκυξ, cuckoo), so called from having been compared to a cuckoo's beak (Fig. 21), is usually formed of four small segments of bone, the most rudimentary parts of the vertebral column. In each of the first three segments may be traced a rudimentary body, articular and transverse processes; the last piece (sometimes the third) is a mere nodule of bone, without distinct processes. All the segments are destitute of pedicles, laminae, and spinous processes, and, consequently, of intervertebral foramina and spinal canal. The first segment is the largest; it resembles the lowermost sacral vertebra, and often exists as a separate piece; the last three, diminishing in size from above downward, are usually blended together so as to form a single bone. The gradual diminution in the size of the pieces gives this bone a triangular form, the base of the triangle joining the end of the sacrum. It presents for examination an anterior and posterior surface, two borders, a base, and an apex. The *anterior surface* is slightly concave, and marked with three transverse grooves, indicating the points of junction of the different pieces. It has attached to it the anterior sacro-coccygeal ligament and Levator ani muscle, and supports the lower end of the rectum. The *posterior surface* is convex, marked by transverse grooves similar to those on the anterior surface; and presents on each side a lineal row of tubercles, the rudimentary articular processes of the coccygeal vertebrae. Of these, the superior pair are large, and are called the *cornua of the coccyx*; they project upward, and articulate with the cornua of the sacrum, the junction between these two

FIG. 21.—Coccyx.

bones completing the fifth posterior sacral foramen for the transmission of the posterior division of the fifth sacral nerve. The *lateral borders* are thin, and present a series of small eminences, which represent the transverse processes of the coccygeal vertebrae. Of these, the first on each side is the largest, flattened from before backward, and often ascends to join the lower part of the thin lateral edge of the sacrum, thus completing the fifth anterior sacral foramen for the transmission of the anterior division of the fifth sacral nerve; the others diminish in size from above downward, and are often wanting. The *borders*

of the coccyx are narrow, and give attachment on each side to the sacro-sciatic ligaments, to the Coccygeus muscles in front of the ligaments, and to the Gluteus maximus behind them. The *base* presents an oval surface for articulation with the sacrum. The *apex* is rounded, and has attached to it the tendon of the external Sphincter muscle. It is occasionally bifid, and sometimes deflected to one or other side.

Development.—The coccyx is developed by *four* centres, one for each piece. Occasionally one of the first three pieces of this bone is developed by two centres, placed side by side. The ossific nuclei make their appearance in the following order: in the first segment, shortly after birth; in the second piece, at from five to ten years; in the third, from ten to fifteen years; in the fourth, from fifteen to twenty years. As age advances these various segments become united with each other from below upward, the union between the first and second segments being frequently delayed until after the age of twenty-five or thirty. At a late period of life, especially in females, the coccyx often becomes joined to the end of the sacrum.

Articulation.—With the sacrum.

Attachment of Muscles.—To four pairs and one single muscle: on either side, the Coccygeus; behind, the Gluteus maximus and Extensor coccygis, when present; at the apex, the Sphincter ani; and in front, the Levator ani.

The Spine in General.

The **Spinal Column**, formed by the junction of the vertebræ, is situated in the median line, at the posterior part of the trunk; its average length is about two feet two or three inches, measuring along the curved anterior surface of the column. Of this length the cervical part measures about five, the dorsal about eleven, the lumbar about seven inches, and the sacrum and coccyx the remainder. The female spine is about one inch less than that of the male.

Viewed in front, it presents two pyramids joined together at their bases, the upper one being formed by all the vertebræ from the second cervical to the last lumbar, the lower one by the sacrum and coccyx. When examined more closely, the upper pyramid is seen to be formed of three smaller pyramids. The uppermost of these consists of the six

FIG. 22.—Lateral view of the spine.

lower cervical vertebræ, its apex being formed by the axis or second cervical, its base by the first dorsal. The second pyramid, which is inverted, is formed by the four upper dorsal vertebræ, the base being at the first dorsal, the smaller end at the fourth. The third pyramid commences at the fourth dorsal, and gradually increases in size to the fifth lumbar.

Viewed laterally (Fig. 22), the spinal column presents several curves, which correspond to the different regions of the column, and are called *cervical*, *dorsal*, *lumbar*, and *pelvic*. The *cervical* curve commences at the apex of the odontoid process, and terminates at the middle of the second dorsal vertebra; it is convex in front, and is the least marked of all the curves. The *dorsal* curve, which is concave forward, commences at the middle of the second, and terminates at the middle of the twelfth dorsal. Its most prominent point behind corresponds to the spine of the seventh dorsal vertebra. The *lumbar* curve commences at the middle of the last dorsal vertebra, and terminates at the sacro-vertebral angle. It is convex anteriorly; the convexity of the lower three vertebræ being much greater than that of the upper two. The *pelvic* curve commences at the sacro-vertebral articulation and terminates at the point of the coccyx. It is concave anteriorly. The dorsal and pelvic curves are the primary curves, and begin to be formed at an early period of foetal life, and are due to the shape of the bodies of the vertebræ. The cervical and lumbar curves are compensatory or secondary, and are developed after birth in order to maintain the erect position. They are due mainly to the shape of the intervertebral disks.

The spine has also a slight lateral curvature, the convexity of which is directed toward the right side. This is most probably produced, as Bichat first explained, chiefly by muscular action, most persons using the right arm in preference to the left, especially in making long-continued efforts, when the body is curved to the right side. In support of this explanation it has been found by Bécларd that in one or two individuals who were left-handed the lateral curvature was directed to the left side.

The movable part of the spinal column presents for examination an anterior, a posterior, and two lateral surfaces; a base, a summit, and spinal canal.

The **anterior surface** presents the bodies of the vertebræ separated in the recent state by the intervertebral disks. The bodies are broad in the cervical region, narrow in the upper part of the dorsal, and broadest in the lumbar region. The whole of this surface is convex transversely, concave from above downward in the dorsal region, and convex in the same direction in the cervical and lumbar regions.

The **posterior surface** presents in the median line the spinous processes. These are short, horizontal, with bifid extremities, in the cervical region. In the dorsal region they are directed obliquely above, assume almost a vertical direction in the middle, and are horizontal below, as are also the spines of the lumbar vertebræ. They are separated by considerable intervals in the loins, by narrower intervals in the neck, and are closely approximated in the middle of the dorsal region. Occasionally one of these processes deviates a little from the median line—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the spine. On either side of the spinous processes, extending the whole length of the column, is the vertebral groove formed by the laminae in the cervical and lumbar regions, where it is shallow, and by the laminae and transverse processes in the dorsal region, where it is deep and broad. In the recent state these grooves lodge the deep muscles of the back. External to the vertebral grooves are the articular processes, and still more externally the transverse process. In the dorsal region the latter processes stand backward, on a plane considerably posterior to the same processes in the cervical and lumbar regions. In the cervical region the transverse processes are placed in front of the articular processes, and on the outer side of the pedicles, between the interver-

tebral foramina. In the dorsal region they are posterior to the pedicles, intervertebral foramina, and articular processes. In the lumbar they are placed also in front of the articular processes, but behind the intervertebral foramina.

The **lateral surfaces** are separated from the posterior by the articular processes in the cervical and lumbar regions, and by the transverse processes in the dorsal. These surfaces present in front the sides of the bodies of the vertebræ, marked in the dorsal region by the facets for articulation with the heads of the ribs. More posteriorly are the intervertebral foramina, formed by the juxtaposition of the intervertebral notches, oval in shape, smallest in the cervical and upper part of the dorsal regions, and gradually increasing in size to the last lumbar. They are situated between the transverse processes in the neck, and in front of them in the back and loins, and transmit the spinal nerves.

The **base** of that portion of the vertebral column formed by the twenty-four movable vertebræ is formed by the under surface of the body of the fifth lumbar vertebra; and the **summit** by the upper surface of the atlas.

The **vertebral or spinal canal** follows the different curves of the spine; it is largest in those regions in which the spine enjoys the greatest freedom of movement, as in the neck and loins, where it is wide and triangular; and narrow and rounded in the back, where motion is more limited.

Surface Form.—The only part of the vertebral column which lies closely under the skin, and so directly influences surface form, is the apices of the spinous processes. These are always distinguishable at the bottom of a median furrow, which, more or less evident, runs down the mesial line of the back from the external occipital protuberance above to the middle of the sacrum below. In the neck the furrow is broad, and terminates in a conspicuous projection, which is caused by the spinous process of the seventh cervical vertebra (*vertebra prominens*). Above this the spinous process of the sixth cervical vertebra may sometimes be seen to form a projection; the other cervical spines are sunken, and are not visible, though the spine of the axis can be felt, and generally also the spines of the third, fourth, and fifth cervical vertebræ. In the dorsal region the furrow is shallow, and during stooping disappears, and then the spinous processes become more or less visible. The markings produced by these spines are small and close together. In the lumbar region the furrow is deep, and the situation of the lumbar spines is frequently indicated by little pits or depressions, especially if the muscles in the loins are well developed and the spine incurved. They are much larger and farther apart than in the dorsal region. In the sacral region the furrow is shallower, presenting a flattened area which terminates below at the most prominent part of the posterior surface of the sacrum, formed by the spinous process of the third sacral vertebra. At the bottom of the furrow may be felt the irregular posterior surface of the bone. Below this, in the deep groove leading to the anus, the coccyx may be felt. The only other portions of the vertebral column which can be felt from the surface are the transverse processes of three of the cervical vertebræ—viz. the first, the sixth, and the seventh. The transverse process of the atlas can be felt as a rounded nodule of bone just below and in front of the apex of the mastoid process, along the anterior border of the sterno-mastoid. The transverse process of the sixth cervical vertebra is of surgical importance. If deep pressure be made in the neck in the course of the carotid artery, opposite the cricoid cartilage, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra can be felt. This has been named *Chassaignac's tubercle*, and against it the carotid artery may be most conveniently compressed by the finger. The transverse process of the seventh cervical vertebra can also often be felt. Occasionally the anterior root, or costal process, is large and segmented off, forming a cervical rib.

Surgical Anatomy.—Occasionally the coalescence of the laminae is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (*dura mater* and *arachnoid*), and sometimes of the spinal cord itself, takes place, constituting a malformation known as *spina bifida*. This disease is most common in the lumbosacral region; but it may occur in the dorsal or cervical region, or the arches throughout the whole length of the canal may remain unapproximated. In some rare cases, in consequence of the non-coalescence of the two primary centres from which the body is formed, a similar condition may occur in front of the canal, the bodies of the vertebræ being found cleft and the tumor projecting into the thorax, abdomen, or pelvis, between the lateral halves of the bodies affected.

The construction of the spinal column of a number of pieces, securely connected together and enjoying only a slight degree of movement between any two individual pieces, though permitting of a very considerable range of movement as a whole, allows a sufficient degree of mobility without any material diminution of strength. The many joints of which the spine is composed, together with the very varied movements to which it is subjected, render it liable to

sprains; but so closely are the individual vertebræ articulated that these sprains are rarely or ever severe, and any amount of violence sufficiently great to produce tearing of the ligaments would tend rather to cause a dislocation or fracture. The further safety of the column and its less liability to injury is provided for by its disposition in curves, instead of in one straight line. For it is an elastic column, and must first bend before it breaks: under these circumstances, being made up of three curves, it represents three columns, and greater force is required to produce bending of a short column than of a longer one that is equal to it in breadth and material. Again, the safety of the column is provided for by the interposition of the intervertebral disk between the bodies of the vertebræ, which act as admirable buffers in counteracting the effects of violent jars or shocks. Fracture-dislocation of the spine may be caused by direct or indirect violence, or by a combination of the two, as when a person, falling from a height, strikes against some prominence and is doubled over it. The fractures from indirect violence are the more common, and here the bodies of the vertebræ are compressed, whilst the arches are torn asunder; whilst in fractures from direct violence the arches are compressed and the bodies of the vertebræ separated from each other. It will therefore be seen that in both classes of injury the spinal marrow is the part least likely to be injured, and may escape damage even where there has been considerable lesion of the bony framework. For, as Mr. Jacobson states, "being lodged in the centre of the column, it occupies neutral ground in respect to forces which might cause fracture. For it is a law in mechanics that when a beam, as of timber, is exposed to breakage and the force does not exceed the limits of the strength of the material, one division resists compression, another laceration of the particles, while the third, between the two, is in a negative condition."¹ Applying this principle to the spine, it will be seen that, whether the fracture-dislocation be produced by direct violence or indirect, one segment, either the anterior or posterior, will be exposed to compression, the other to laceration, and the intermediate part, where the cord is situated, will be in a neutral state. When a fracture-dislocation is produced by indirect violence the displacement is almost always the same, the upper segment being driven forward on the lower, so that the cord is compressed between the body of the vertebra below and the arch of the vertebra above.

The parts of the spine most liable to be injured are (1) the dorsi-lumbar region, for this part is near the middle of the column, and there is therefore a greater amount of leverage, and moreover the portion above is comparatively fixed, and the vertebræ which form it, though much smaller, have nevertheless to bear almost as great a weight as those below; (2) the cervico-dorsal region, because here the flexible cervical portion of the spine joins the more fixed dorsal region; and (3) the atlanto-axial region, because it enjoys an extensive range of movement, and, being near the skull, is influenced by violence applied to the head. In fracture-dislocation it has been proposed to trephine the spine and remove portions of the laminae and spinous processes. The operation can only be of use when the paralysis is due to the pressure of bone or the effusion of blood, and not to cases, which are by far the most common, where the cord is crushed to a pulp. And even in those cases where the cord is compressed by bone the portion of displaced bone which presses on the cord is generally the body of the vertebra below, and is therefore inaccessible to operation. The operative proceeding is one of great severity, involving an extensive and deep wound and great risk of septic meningitis, and, as the advantages to be derived from it are exceedingly problematical and confined to a very few cases, it is not often resorted to. Trephining has also been resorted to in some cases of paraplegia due to Pott's disease of the spine. Here the paralysis is due to the pressure of inflammatory products, and where this is new scar-tissue, formed by the organization of granulation tissue, its removal has been attended with a very considerable amount of success.

THE SKULL.

The Skull is supported on the summit of the vertebral column, and is of an oval shape, wider behind than in front. It is composed of a series of flattened or irregularly shaped bones which, with one exception (the lower jaw), are immovably joined together. It is divided into two parts, the Cranium and the Face, the former of which constitutes a case for the accommodation and protection of the brain, while opening on the face are the orifices of the nose and mouth; between the cranium above and the face below the orbital cavities are situated. The Cranium (*κροῖον*, a helmet) is composed of eight bones—viz., the *occipital*, two *parietal*, *frontal*, two *temporal*, *sphenoid*, and *ethmoid*. The Face is composed of fourteen bones—viz., the two *nasal*, two *superior maxillary*, two *lachrymal*, two *malar*, two *palate*, two *inferior turbinated*, *vomer*, and *inferior maxillary*. The *ossiculi auditūs*, the *teeth*, and *Wormian bones* are not included in this enumeration.

¹ Holmes's *System of Surgery*, vol. i., p. 529, 1883.

The Hyoid Bone, situated at the root of the tongue and attached to the base of the skull by ligaments, has also to be considered in this section.

THE CRANIUM.

The Occipital Bone.

The Occipital Bone (*ob, caput*, against the head) is situated at the back part

FIG. 23.—Occipital bone. Outer surface.

and base of the cranium, is trapezoid in shape and is much curved on itself (Fig. 23). It presents at its front and lower part a large oval aperture, the *foramen magnum*, by which the cranial cavity communicates with the spinal canal. The portion of bone behind this opening is flat and expanded and forms the *tabula*; the portion in front is a thick, elongated mass of bone, the *basilar process*; while on either side of the foramen are situated processes bearing the

condyles, by which the bone articulates with the atlas. These processes are known as the *condylar portions*. It presents for examination two surfaces, four borders, and four angles.

The **external surface** is convex. Midway between the summit of the bone and the posterior margin of the foramen magnum is a prominent tubercle, the *external occipital protuberance*, and, descending from it as far as the foramen, a vertical ridge, the *external occipital crest*. This protuberance and crest give attachment to the Ligamentum nuchæ, and vary in prominence in different skulls. Passing outward from the occipital protuberance is a semicircular ridge on each side, the *superior curved line*. Above this line there is often a second less distinctly marked ridge, called the *highest curved line (linea suprema)*; to it the epicranial aponeurosis is attached. The bone between these two lines is smoother and denser than the rest of the surface. Running parallel with these from the middle of the crest is another semicircular ridge on each side, the *inferior curved lines*. The surface of the bone above the linea suprema is rough and porous, and in the recent state is covered by the Occipito-frontalis muscle, while the superior and inferior curved lines, together with the surfaces of bone between and below them, serve for the attachment of several muscles. The superior curved line gives attachment internally to the Trapezius, externally to the muscular origin of the Occipito-frontalis, and to the Sterno-cleido-mastoid to the extent shown in Fig. 23; the depressions between the curved lines to the Complexus internally, the Splenius capitis and Obliquus capitis superior externally. The inferior curved line and the depressions below it afford insertion to the Rectus capitis posticus, major and minor.

The **foramen magnum** is a large, oval aperture, its long diameter extending from before backward. It transmits the medulla oblongata and its membranes, the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipito-axial ligaments. Its back part is wide for the transmission of the medulla, and the corresponding margin rough for the attachment of the dura mater enclosing it; the fore part is narrower, being encroached upon by the condyles; it has projecting toward it, from below, the odontoid process, and its margins are smooth and bevelled internally to support the medulla oblongata. On each side of the foramen magnum are the *condyles*, for articulation with the atlas; they are convex, oval, or reniform in shape, and directed downward and outward; they converge in front, and encroach slightly upon the anterior segment of the foramen. On the inner border of each condyle is a rough tubercle for the attachment of the ligaments (*check*) which connect this bone with the odontoid process of the axis; whilst external to them is a rough tubercular prominence, the *transverse* or *jugal process*, channelled in front by a deep notch, which forms part of the jugular foramen or foramen lacerum posterius. The under surface of this process presents an eminence which represents the *paramastoid process* of some mammals. The eminence is occasionally large, and extends as low as the transverse process of the atlas. This surface affords attachment to the Rectus capitis lateralis muscle and to the lateral occipito-atlantal ligament; its upper or cerebral surface presents a deep groove which lodges part of the lateral sinus, whilst its external surface is marked by a quadrilateral rough facet, covered with cartilage in the fresh state, and articulating with a similar surface on the petrous portion of the temporal bone. On the outer side of each condyle, near its fore part, is a foramen, the *anterior condyloid*; it is directed downward, outward, and forward, and transmits the hypoglossal nerve, and occasionally a meningeal branch of the ascending pharyngeal artery. This foramen is sometimes double. Behind each condyle is a fossa,¹ sometimes perforated at the bottom by a foramen, the *posterior condyloid*, for the transmission of a vein to the lateral sinus. In front of the foramen magnum is a strong quadrilateral plate of bone, the *basilar process*, wider behind than in front; its under surface, which is rough, presenting in the median line a tubercular ridge,

¹ This fossa presents many variations in size. It is usually shallow, and the foramen small; occasionally wanting on one or both sides. Sometimes both fossa and foramen are large, but confined to one side only; more rarely, the fossa and foramen are very large on both sides.

the *pharyngeal spine*, for the attachment of the tendinous raphe and Superior constrictor of the pharynx; and on each side of it rough depressions for the attachment of the *Rectus capitis anticus, major and minor*.

The **Internal or Cerebral Surface** (Fig. 24) is deeply concave. The posterior part or tabular is divided by a crucial ridge into four fossæ. The two superior fossæ receive the occipital lobes of the cerebrum, and present slight eminences and depressions corresponding to their convolutions. The two inferior, which receive the hemispheres of the cerebellum, are larger than the former, and comparatively smooth; both are marked by slight grooves for the lodgment of arteries. At the point of meeting of the four divisions of the crucial ridge is an eminence, the *internal occipital protuberance*. It nearly corresponds to that on the outer surface, and is perforated by one or more large vascular foramina. From this eminence the superior division of the crucial ridge runs upward to the superior angle of the bone; it presents a deep groove for the superior longitudinal sinus, the margins of which give attachment to the *falx cerebri*. The inferior division, the *internal occipital crest*, runs to the posterior margin of the foramen magnum,

FIG. 24.—Occipital bone. Inner surface.

on the edge of which it becomes gradually lost; this ridge, which is bifurcated below, serves for the attachment of the *falx cerebelli*. It is usually marked by a single groove, which commences at the back part of the foramen magnum and lodges the occipital sinus. Occasionally the groove is double where two sinuses exist. The transverse grooves pass outward to the lateral angles; they are deeply channelled, for the lodgment of the lateral sinuses, their prominent margins afford-

ing attachment to the tentorium cerebelli.¹ At the point of meeting of these grooves is a depression, the *torcular Herophili*,² placed a little to one or the other side of the internal occipital protuberance. More anteriorly is the foramen magnum, and on each side of it, but nearer its anterior than its posterior part, the internal openings of the anterior condyloid foramen; the internal openings of the posterior condyloid foramina are a little external and posterior to them, protected by a small arch of bone. At this part of the internal surface there is a very deep groove in which the posterior condyloid foramen, when it exists, has its termination. This groove is continuous, in the complete skull, with the transverse groove on the posterior part of the bone, and lodges the end of the same sinus, the lateral. In front of the foramen magnum is the basilar process, presenting a shallow depression, the *basilar groove*, which slopes from behind, upward and forward, and supports the medulla oblongata and part of the pons Varolii, and on each side of the basilar process is a narrow channel, which, when united with a similar channel on the petrous portion of the temporal bone, forms a groove which lodges the inferior petrosal sinus.

Angles.—The *superior* angle is received into the interval between the posterior superior angles of the two parietal bones: it corresponds with that part of the skull in the fœtus which is called the *posterior fontanelle*. The *inferior* angle is represented by the square-shaped surface of the basilar process. At an early period of life a layer of cartilage separates this part of the bone from the sphenoid, but in the adult the union between them is osseous. The *lateral* angles correspond to the outer ends of the transverse grooves, and are received into the interval between the posterior inferior angles of the parietal and the mastoid portion of the temporal.

Borders.—The *superior* border extends on each side from the superior to the lateral angle, is deeply serrated for articulation with the parietal bone, and forms, by this union, the lambdoid suture. The *inferior* border extends from the lateral to the inferior angle; its upper half is rough, and articulates with the mastoid portion of the temporal, forming the masto-occipital suture; the inferior half articulates with the petrous portion of the temporal, forming the petro-occipital suture; these two portions are separated from one another by the jugular process. In front of this process is a deep notch, which, with a similar one on the petrous portion of the temporal, forms the *foramen lacerum posterius* or *jugular foramen*. This notch is occasionally subdivided into two parts by a small process of bone,

and it generally presents an aperture at its upper part, the internal opening of the posterior condyloid foramen.

Structure.—The occipital bone consists of two compact laminæ, called the *outer* and *inner tables*, having between them the diploic tissue; this bone is especially thick at the ridges, protuberances, condyles, and anterior part of the basilar process; while at the bottom of the fossæ, especially the inferior, it is thin, semi-transparent, and destitute of diploë.

Development (Fig. 25).—At birth the bone consists of four distinct

FIG. 25.—Development of occipital bone. By seven centres.

parts: a *tabular* or expanded portion, which lies behind the foramen magnum; two *condylar* parts, which form the sides of the foramen; and a *basilar* part, which lies in front of the foramen. The number of nuclei for the tabular part vary. As

¹ Usually one of the transverse grooves is deeper and broader than the other; occasionally, both grooves are of equal depth and breadth, or both equally indistinct. The broader of the two transverse grooves is nearly always continuous with the vertical groove for the superior longitudinal sinus.

² The columns of blood coming in different directions were supposed to be *pressed* together at this point (*torcular*, a wine-press).

a rule, there are four, but there may be only one (Blandin) or as many as eight (Meckel). They appear about the eighth week of fœtal life, and soon unite to form a single piece, which is, however, fissured in the direction indicated in the figure. The basilar and two condyloid portions are each developed from a single nucleus, which appears a little later. The upper portion of the tabular surface—that is to say, the portion above the transverse fissure—is developed from membrane, and may remain separated from the rest of the bone throughout life, when it constitutes the *interparietal bone*; the rest of the bone is developed from cartilage. At about the fourth year the tabular and the two condyloid pieces join, and about the sixth year the bone consists of a single piece. At a later period, between the eighteenth and twenty-fifth years, the occipital and sphenoid become united, forming a single bone.

Articulations.—With six bones: two parietal, two temporal, sphenoid, and atlas.

Attachment of Muscles.—To twelve pairs: to the superior curved line are attached the Occipito-frontalis, Trapezius, and Sterno-cleido-mastoid. To the space between the curved lines, the Complexus,¹ Splenius capitis, and Obliquus capitis superior; to the inferior curved line, and the space between it and the foramen magnum, the Rectus capitis posticus, major and minor; to the transverse process, the Rectus capitis lateralis; and to the basilar process, the Rectus capitis anticus, major and minor, and Superior constrictor of the pharynx.

FIG. 26.—Left parietal bone. External surface.

The Parietal Bones.

The **Parietal Bones** (*paries*, a wall) form, by their union, the sides and roof of the skull. Each bone is of an irregular quadrilateral form, and presents for examination two surfaces, four borders, and four angles.

¹ To these the Biventer cervicis should be added, if it is regarded as a separate muscle.

Surfaces.—The *external surface* (Fig. 26) is convex, smooth, and marked about its centre by an eminence called the *parietal eminence*, which indicates the point where ossification commenced. Crossing the middle of the bone in an arched direction are two well-marked curved lines or ridges, the *upper* and *lower temporal ridges*; the former gives attachment to the temporal fascia, while the latter indicates the upper limit of the origin of the temporal muscle. Above these ridges the surface of the bone is rough and porous, and covered by the aponeurosis of the Occipito-frontalis; between them the bone is smoother and more polished than the rest; below them the bone forms part of the temporal fossa, and affords attachment to the temporal muscle. At the back part of the superior border, close to the sagittal suture, is a small foramen, the *parietal foramen*, which transmits a vein to the superior longitudinal sinus, and sometimes a small branch of the occipital artery. Its existence is not constant, and its size varies considerably.

The *internal surface* (Fig. 27), concave, presents depressions for lodging the convolutions of the cerebrum and numerous furrows for the ramifications of the middle meningeal artery; the latter runs upward and backward from the

FIG. 27.—Left parietal bone. Internal surface.

anterior inferior angle and from the central and posterior part of the lower border of the bone. Along the upper margin is part of a shallow groove, which, when joined to the opposite parietal, forms a channel for the superior longitudinal sinus, the elevated edges of which afford attachment to the falx cerebri. Near the groove are seen several depressions, especially in the skulls of old persons; they lodge the Pacchionian bodies. The internal opening of the parietal foramen is also seen when that aperture exists.

Borders.—The *superior*, the longest and thickest, is dentated to articulate with its fellow of the opposite side, forming the sagittal suture. The *inferior* is divided into three parts: of these, the anterior is thin and pointed, bevelled at the expense of the outer surface, and overlapped by the tip of the great wing of the sphenoid; the middle portion is arched, bevelled at the expense of the outer surface, and

overlapped by the squamous portion of the temporal; the posterior portion is thick and serrated for articulation with the mastoid portion of the temporal. The *anterior* border, deeply serrated, is bevelled at the expense of the outer surface above and of the inner below; it articulates with the frontal bone, forming the *coronal suture*. The *posterior* border, deeply denticulated, articulates with the occipital, forming the *lambdoid suture*.

Angles.—The *anterior superior* angle, thin and pointed, corresponds with that portion of the skull which in the foetus is membranous and is called the *anterior fontanelle*. The *anterior inferior* angle is thin and lengthened, being received in the interval between the great wing of the sphenoid and the frontal. Its inner surface is marked by a deep groove, sometimes a canal, for the anterior branch of the middle meningeal artery. The *posterior superior* angle corresponds with the junction of the sagittal and lambdoid sutures. In the foetus this part of the skull is membranous, and is called the *posterior fontanelle*. The *posterior inferior* angle articulates with the mastoid portion of the temporal bone, and generally presents on its inner surface a broad, shallow groove for lodging part of the lateral sinus.

Development.—The parietal bone is formed in membrane, being developed by one centre, which corresponds with the parietal eminence, and makes its first appearance about the seventh or eighth week of foetal life. Ossification gradually extends from the centre to the circumference of the bone: the angles are consequently the parts last formed, and it is in their situation that the fontanelles exist previous to the completion of the growth of the bone. Occasionally the parietal bone is divided into two parts, upper and lower, by an antero-posterior suture.

Articulations.—With five bones: the opposite parietal, the occipital, frontal, temporal, and sphenoid.

Attachment of Muscles.—One only, the Temporal.

The Frontal Bone.

The **Frontal Bone** (*frons*, the forehead) resembles a cockle-shell in form, and consists of two portions—a *vertical* or *frontal* portion situated at the anterior part of the cranium, forming the forehead; and a *horizontal* or *orbito-nasal* portion which enters into the formation of the roof of the orbits and nasal fossæ.

Vertical Portion.—*External Surface* (Fig. 28).—In the median line, traversing the bone from the upper to the lower part, is occasionally seen a slightly-elevated ridge, and in young subjects a suture, which represents the line of union of the two lateral halves of which the bone consists at an early period of life; in the adult this suture is usually obliterated and the bone forms one piece; traces of the obliterated suture are, however, generally perceptible at the lower part. On either side of this ridge, a little below the centre of the bone, is a rounded eminence, the *frontal eminence*. These eminences vary in size in different individuals, and are occasionally unsymmetrical in the same subject. They are especially prominent in cases of well-marked cerebral development. The whole surface of the bone above this part is smooth, and covered by the aponeurosis of the Occipito-frontalis muscle. Below the frontal eminence, and separated from it by a slight groove, is the *superciliary ridge*, broad internally, where it is continuous with the nasal eminence, but less distinct as it arches outward. These ridges are caused by the projection outward of the frontal air sinuses,¹ and give attachment to the Orbicularis palpebrarum and Corrugator supercilii. Between the two superciliary ridges is a smooth surface, the *glabella* or *nasal eminence*. Beneath the superciliary ridge is the *supraorbital arch*, a curved and prominent margin, which forms

¹ Some confusion is occasioned to students commencing the study of anatomy by the name "sinuses" having been given to two perfectly different kinds of spaces connected with the skull. It may be as well, therefore, to state here, at the outset, that the "sinuses" in the interior of the cranium which produce the grooves on the inner surface of the bones are venous channels along which the blood runs in its passage back from the brain, while the "sinuses" external to the cranial cavity (the frontal, sphenoidal, ethmoidal, and maxillary) are hollow spaces in the bones themselves which communicate with the nostrils, and contain air.

the upper boundary of the orbit and separates the vertical from the horizontal portion of the bone. The outer part of the arch is sharp and prominent, affording to the eye, in that situation, considerable protection from injury; the inner part is less prominent. At the junction of the internal and middle third of this arch is a notch, sometimes converted into foramen, and called the *supraorbital notch* or *foramen*. It transmits the supraorbital artery, vein, and nerve. A small aperture is seen in the upper part of the notch, which transmits a vein from the diploë to join the supraorbital vein. The supraorbital arch terminates externally in the *external angular process* and internally in the *internal angular process*. The external angular process is strong, prominent, and articulates with the malar bone; running upward and backward from it are two well-marked lines, which, commencing together from the external angular process, soon diverge from each other and run in a curved direction across the bone. These are the *upper* and *lower temporal ridges*; the upper gives attachment to the temporal fascia, the

FIG. 28.—Frontal bone. Outer surface.

lower to the temporal muscle. Beneath them is a slight concavity that forms the anterior part of the temporal fossa and gives origin to the Temporal muscle. The internal angular processes are less marked than the external, and articulate with the lachrymal bones. Between the internal angular processes is a rough, uneven interval, the *nasal notch*, which articulates in the middle line with the nasal bone, and on either side with the nasal process of the superior maxillary bone. From the concavity of this notch projects a process, the *nasal process*, which extends beneath the nasal bones and nasal processes of the superior maxillary bones and supports the bridge of the nose. On the under surface of this is a long pointed process, the *nasal spine*, and on either side a small grooved surface enters into the formation of the roof of the nasal fossa. The nasal spine forms part of the septum of the nose, articulating in front with the nasal bones and behind with the perpendicular plate of the ethmoid.

Internal Surface (Fig. 29).—Along the middle line is a vertical groove, the edges of which unite below to form a ridge, the *frontal crest*; the groove lodges the superior longitudinal sinus, whilst its margins afford attachment to the falx cerebri. The crest terminates below at a small notch which is converted into a foramen by articulation with the ethmoid. It is called the *foramen cæcum*, and varies in size in different subjects: it is sometimes partially or completely impervious, lodges a process of the falx cerebri, and when open transmits a vein from the lining membrane of the nose to the superior longitudinal sinus. On either side of the groove the bone is deeply concave, presenting depressions for the convolutions of the brain, and numerous small furrows for lodging the ramifications of the anterior meningeal arteries. Several small, irregular fossæ are seen also on either side of the groove, for the reception of the Pacchionian bodies.

Horizontal Portion.—This portion of the bone consists of two thin plates, the *orbital plates*, which form the vault of the orbit, separated from one another by a median gap, the ethmoidal notch. The *external surface* of each orbital plate consists of a smooth, concave, triangular lamina of bone, marked at its anterior and external part (immediately beneath the external angular

FIG. 29.—Frontal bone. Inner surface.

process) by a shallow depression, the *lachrymal fossa*, for lodging the lachrymal gland; and at its anterior and internal part by a depression (sometimes a small tubercle), the *trochlear fossa*, for the attachment of the cartilaginous pulley of the Superior oblique muscle of the eye. The ethmoidal notch separates the two orbital plates; it is quadrilateral, and filled up, when the bones are united, by the cribriform plate of the ethmoid. The margins of this notch present several half-cells, which, when united with corresponding half-cells on the upper surface of the ethmoid, complete the ethmoidal cells; two grooves are also seen crossing these

edges transversely; they are converted into canals by articulation with the ethmoid, and are called the *anterior* and *posterior ethmoidal* canals: they open on the inner wall of the orbit. The anterior one transmits the nasal nerve and anterior ethmoidal vessels, the posterior one the posterior ethmoidal vessels. In front of the ethmoidal notch, on either side of the nasal spine, are the openings of the frontal sinuses. These are two irregular cavities, which extend upward and outward, a variable distance, between the two tables of the skull, and are separated from one another by a thin, bony septum, which is often displaced to one side. They give rise to the prominences above the supraorbital arches called the *superciliary ridges*. In the child they are generally absent, and they become gradually developed as age advances. These cavities vary in size in different persons, are larger in men than in women, and are frequently of unequal size on the two sides, the right being commonly the larger. They are lined by mucous membrane, and communicate with the nose by the infundibulum, and occasionally with each other by apertures in their septum.

The **internal surface of the horizontal portion** presents the convex upper surfaces of the orbital plates, separated from each other in the middle line by the ethmoidal notch, and marked by eminences and depressions for the convolutions of the frontal lobes of the brain.

Borders.—The border of the vertical portion is thick, strongly serrated, bevelled at the expense of the internal table above, where it rests upon the parietal bones, and at the expense of the external table at each side, where it receives the lateral pressure of those bones; this border is continued below into a triangular rough surface which articulates with the great wing of the sphenoid. The border of the horizontal portion is thin, serrated, and articulates with the lesser wing of the sphenoid.

Structure.—The vertical portion and external angular processes are very thick, consisting of diploic tissue contained between two compact laminæ. The horizontal portion is thin, translucent, and composed entirely of compact tissue; hence the facility with which instruments can penetrate the cranium through this part of the orbit.

Development (Fig. 30).—The frontal bone is formed in membrane, being developed by *two* centres, one for each lateral half, which make their appearance about the seventh or eighth week, above the orbital arches. From this point ossification extends, in a radiating manner, upward into the forehead and backward over the orbit. At birth the bone consists of two pieces, which afterward become united, along the middle line, by a suture which runs from the vertex to the root of the nose. This suture usually becomes obliterated within a few years after birth; but

FIG. 30.—Frontal bone at birth. Developed by two lateral halves.

it occasionally remains throughout life, constituting the *metopic* suture. Secondary centres of ossification appear for the nasal spine—one on either side at the internal angular process where it articulates with the lachrymal bone; and sometimes there is one on either side at the lower end of the coronal suture. This latter centre sometimes remains ununited, and is known as the pterion ossicle, or it may join with the parietal, sphenoid, or temporal bone.

Articulations.—With twelve bones: two parietal, the sphenoid, the ethmoid, two nasal, two superior maxillary, two lachrymal, and two malar.

Attachment of Muscles.—To three pairs: the Corrugator supercilii, Orbicularis palpebrarum, and Temporal, on each side.

runs from the upper border of the zygoma backward over the external auditory meatus. It is termed the *supra-mastoid crest*, and forms the posterior part of the lower temporal ridge. At the junction of the anterior root with the zygoma is a projection, called the *tubercle*, for the attachment of the external lateral ligament of the lower jaw; and between the anterior and middle roots is an oval depression, forming part of the glenoid fossa ($\gamma\lambda\eta\nu\chi$, a socket), for the reception of the condyle of the lower jaw. This fossa is bounded, in front, by the eminentia articularis; behind, by the tympanic plate, which separates it from the external auditory meatus; it is divided into two parts by a narrow slit, the *Glaserian fissure*. The anterior or mandibular part, formed by the squamous portion of the bone, is smooth, covered in the recent state with cartilage, and articulates with the condyle of the lower jaw. This part of the glenoid fossa presents posteriorly a small conical eminence, the *post-glenoid process*, already referred to. This process is the representative of a prominent tubercle which, in some of the mammalia, descends behind the condyle of the jaw, and prevents it being displaced backward during mastication (Humphry). The posterior part of the glenoid fossa, which lodges a portion of the parotid gland, is formed chiefly by the *tympanic plate*, which constitutes the anterior wall of the tympanum and external auditory meatus. The plate of bone terminates above in the Glaserian fissure, and below forms a sharp edge, the *vaginal process*, which gives origin to some of the fibres of the Tensor palati muscle. The Glaserian fissure, which leads into the tympanum, lodges the processus gracilis of the malleus, and transmits the tympanic branch of the internal maxillary artery. The chorda tympani nerve passes through a separate canal, parallel to the Glaserian fissure (*canal of Huguier*), on the outer side of the Eustachian tube, in the retiring angle between the squamous and petrous portions of the temporal bone.¹

FIG. 32.—Left temporal bone. Inner surface.

The **internal surface** of the squamous portion (Fig. 32) is concave, presents

¹ This small fissure must not be confounded with the large canal which lies above the Eustachian tube and transmits the Tensor tympani muscle.

numerous eminences and depressions for the convolutions of the cerebrum, and two well-marked grooves for the branches of the middle meningeal artery.

Borders.—The superior border is thin, bevelled at the expense of the internal surface, so as to overlap the lower border of the parietal bone, forming the squamous suture. The anterior inferior border is thick, serrated, and bevelled, alternately at the expense of the inner and outer surfaces, for articulation with the great wing of the sphenoid.

The **Mastoid Portion** (*μαστός*, a nipple or teat) is situated at the posterior part of the bone; its outer surface is rough, and gives attachment to the Occipito-frontalis and Retrahens aurem muscles. It is perforated by numerous foramina; one of these, of large size, situated at the posterior border of the bone, is termed the *mastoid foramen*; it transmits a vein to the lateral sinus and a small artery from the occipital to supply the dura mater. The position and size of this foramen are very variable. It is not always present; sometimes it is situated in the occipital bone or in the suture between the temporal and the occipital. The mastoid portion is continued below into a conical projection, the *mastoid process*, the size and form of which vary somewhat. This process serves for the attachment of the Sterno-mastoid, Splenius capitis, and Trachelo-mastoid muscles. On the inner side of the mastoid process is a deep groove, the *digastric fossa*, for the attachment of the Digastric muscle; and, running parallel with it, but more internal, the *occipital groove*, which lodges the occipital artery. The internal surface of the mastoid portion presents a deep, curved groove, the *fossa sigmoidea*, which lodges part of the lateral sinus; and into it may be seen opening the mastoid fora-

FIG. 33.—Section through the petrous and mastoid portions of the temporal bone, showing the communication of the cavity of the tympanum with the mastoid antrum.

men. The groove for the lateral sinus is separated from the innermost of the mastoid air-cells by only a thin lamina of bone, and even this may be partly deficient. A section of the mastoid process shows it to be hollowed out into a number of cellular spaces, communicating with each other, called the *mastoid cells*, which exhibit the greatest possible variety as to their size and number. At the upper and front part of the bone these cells are large and irregular, and contain air. They diminish in size toward the lower part of the bone, those situated at the apex of the mastoid process being quite small and usually containing marrow. Occasionally they are entirely absent, and the mastoid is solid throughout. In addition to these may be seen a large irregular cavity (Fig. 33),

situated at the upper and front part of the section. It is called the *mastoid antrum*, and must be distinguished from the mastoid cells, though it communicates with them. It is filled with air, and is lined with a prolongation of the mucous membrane of the tympanum, which extends into it through an opening, by which it communicates with the cavity of the tympanum. The mastoid antrum is bounded above by a thin plate of bone, which separates it from the middle fossa of the base of the skull on the anterior surface of the petrous portion of the temporal bone; below by the mastoid process; externally by the squamous portion of the bone just below the supra-mastoid crest; and internally by the external semicircular canal of the internal ear which projects into its cavity. The opening by which it communicates with the tympanum is situated at the superior internal angle of the posterior wall of that cavity, and opens into that portion of the tympanic cavity which is known as the *attic* or *epitympanic recess*; that is to say, that portion of the tympanum which is above the level of the *membrana tympani*.

The mastoid cells, like the other sinuses of the cranium, are not developed until after puberty; hence the prominence of this process in the adult: the mastoid antrum, on the other hand, is of large size at birth.

In consequence of the communication which exists between the tympanum and mastoid cells, inflammation of the lining membrane of the former cavity may easily travel backward to that of the antrum, leading to caries and necrosis of their walls and the risk of transference of the inflammation to the lateral sinus or encephalon.

Borders.—The superior border of the mastoid portion is broad and rough, its serrated edge sloping outward, for articulation with the posterior inferior angle of the parietal bone. The posterior border, also uneven and serrated, articulates with the inferior border of the occipital bone between its lateral angle and jugular process.

The **Petrous Portion** (*πέτρος*, a stone), so named from its extreme density and hardness, is a pyramidal process of bone wedged in at the base of the skull between the sphenoid and occipital bones. Its direction from without is inward, forward, and a little downward. It presents for examination a base, an apex, three surfaces, and three borders, and contains, in its interior, the essential parts of the organ of hearing. The *base* is applied against the internal surface of the squamous and mastoid portions, its upper half being concealed; but its lower half is exposed by the divergence of those two portions of the bone, which brings into view the oval expanded orifice of a canal leading into the tympanum, the *meatus auditorius externus*. The curved tympanic plate forms the anterior wall, the floor, and a part of the posterior wall of this meatus, while the squamous temporal completes it above and behind. The entrance to the meatus is bounded throughout the greater part of its circumference by the *auditory process*, which is the name applied to the free rough margin of the tympanic plate, and which gives attachment to the cartilaginous portion of the meatus. Superiorly the entrance to the meatus is limited by the posterior root of the zygoma.

The **apex** of the petrous portion, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid and the basilar process of the occipital; it presents the anterior or internal orifice of the carotid canal, and forms the posterior and external boundary of the foramen lacerum medium.

The **anterior surface** of the petrous portion (Fig. 32) forms the posterior part of the middle fossa of the skull. This surface is continuous with the squamous portion, to which it is united by a suture, the *petro-squamous suture*, the remains of which are distinct even at a late period of life. It presents six points for examination: 1, an eminence near the centre, which indicates the situation of the superior semicircular canal; 2, in front and a little to the outer side of this eminence a depression indicating the position of the tympanum; here the layer of bone which separates the tympanum from the cranial cavity is extremely thin, and is known as the *tegmen tympani*; 3, a shallow groove, sometimes

double, leading outward and backward to an oblique opening, the *hiatus Fallopii*, for the passage of the greater petrosal nerve and the petrosal branch of the middle meningeal artery; 4, a smaller opening, occasionally seen external to the latter, for the passage of the smaller petrosal nerve; 5, near the apex of the bone, the termination of the carotid canal, the wall of which in this situation is deficient in front; 6, above this canal a shallow depression for the reception of the Gasserian ganglion.

The posterior surface forms the front part of the posterior fossa of the skull, and is continuous with the inner surface of the mastoid portion of the bone. It presents three points for examination: 1. About its centre, a large orifice, the *meatus auditorius internus*, whose size varies considerably; its margins are smooth and rounded, and it leads into a short canal, about four lines in length, which runs directly outward and is closed by a vertical plate, the *lamina cribrosa*, which is divided by a horizontal crest, the *crista falciformis*, into two unequal portions. Each portion is subdivided by a little vertical crest into two parts, named respectively anterior and posterior. The lower portion presents three sets of foramina; one group just below the posterior part of the crest, the *area cribrosa media*, consisting of a number of small openings for the nerves to the sacculæ; below and posterior to this, the *foramen singulare*, or opening for the nerve to the posterior semicircular canal; in front and below the first, the *tractus spiralis foraminosus*, consisting of a number of small spirally arranged openings which terminate in the canalis centralis cochleæ and transmit the nerve to the cochlea; the upper portion, that above the crista, presents behind a series of small openings, the *area cribrosa superior*, for the passage of filaments to the utricle and superior and external semicircular canal, and, in front, one large opening, the commencement of the aquæductus Fallopii, for the passage of the facial nerve. 2. Behind the meatus auditorius, a small slit, almost hidden by a thin plate of bone, leading to a canal, the *aquæductus vestibuli*, which transmits the *ductus endolymphaticus* together with a small artery and vein. In the interval between these two openings, but above them, is an angular depression which lodges a process of the dura mater, and transmits a small vein into the cancellous tissue of the bone. In the child this depression is represented by a large fossa, the *floccular fossa*, which extends backward as a blind tunnel under the superior semicircular canal.

The inferior or basilar surface (Fig. 35) is rough and irregular, and forms part of the base of the skull. Passing from the apex to the base, this surface presents eleven points for examination: 1, a rough surface, quadrilateral in form, which serves partly for the attachment of the Levator palati and Tensor tympani muscles; 2, the large, circular aperture of the carotid canal, which ascends at first vertically, and then, making a bend, runs horizontally forward and inward; it transmits the internal carotid artery and the carotid plexus; 3, the *aquæductus cochleæ*, a small, triangular opening, lying on the inner side of the latter, close to the posterior border of the petrous portion; it transmits a vein from the cochlea which joins the internal jugular; 4, behind these openings a deep depression, the *jugular fossa*, which varies in depth and size in different skulls; it lodges the

FIG. 34.—Diagrammatic view of the Fundus of the internal auditory meatus (Testut): 1. Falciform crest. 2. Anterior superior cribriform area. 3. Internal opening of the Aquæductus Fallopii. 4. Vertical crest which separates the anterior and posterior superior cribriform areas, 4' openings for nerve-filaments. 5. Anterior inferior cribriform area. 5'. Spirally arranged, sieve-like openings for the nerves to the cochlea. 6. Opening of the central canal of the cochlea. 7. Crest which separates the anterior and posterior inferior cribriform areas. 8. Posterior inferior cribriform area. 9. Orifices for the branches of the nerve to the sacculæ. 10. Foramen singulare of Morgagni, with the anterior portion of the canal which gives passage to the nerve to the posterior semicircular canal.

lateral sinus, and, with a similar depression on the margin of the jugular process of the occipital bone, forms the foramen lacerum posterius or jugular foramen; 5, a small foramen for the passage of Jacobson's nerve (the tympanic branch of the glosso-pharyngeal): this foramen is seen in front of the bony ridge dividing

FIG. 35.—Petræous portion. Inferior surface.

the carotid canal from the jugular fossa; 6, a small foramen on the wall of the jugular fossa, for the entrance of the auricular branch of the pneumogastric (Arnold's) nerve; 7, behind the jugular fossa a smooth, square-shaped facet, the *jugular surface*; it is covered with cartilage in the recent state, and articulates with the jugular process of the occipital bone; 8, the *vaginal process*, a very broad, sheath-like plate of bone, which extends backward from the carotid canal and gives attachment to part of the Tensor palati muscle; this plate divides behind into two laminæ, the outer of which is continuous with the tympanic plate, the inner with the jugular process; 9, between these laminæ is the ninth point for examination, the *styloid process*, a sharp spine, about an inch in length: it is directed downward, forward, and inward, varies in size and shape, and sometimes consists of several pieces united by cartilage; it affords attachment to three muscles, the Stylo-pharyngeus, Stylo-hyoideus, and Stylo-glossus, and two ligaments, the stylo-hyoid and stylo-maxillary; 10, the *stylo-mastoid foramen*, a rather large orifice, placed between the styloid and mastoid processes: it is the termination of the aquæductus Fallopii, and transmits the facial nerve and stylo-mastoid artery; 11, the *auricular fissure*, situated between the tympanic plate and mastoid processes, for the exit of the auricular branch of the pneumogastric nerve.

Borders.—The *superior*, the longest, is grooved for the superior petrosal sinus, and has attached to it the tentorium cerebelli; at its inner extremity is a semilunar notch, upon which the fifth nerve lies. The *posterior* border is intermediate in length between the superior and the anterior. Its inner half is marked by a groove, which, when completed by its articulation with the occipital, forms the channel

for the inferior petrosal sinus. Its outer half presents a deep excavation—the *jugular fossa*—which, with a similar notch on the occipital, forms the foramen lacerum posterius. A projecting eminence of bone occasionally stands out from the centre of the notch, and divides the foramen into two parts. The *anterior* border is divided into two parts—an outer joined to the squamous portion by a suture, the remains of which are distinct; an inner, free, articulating with the spinous process of the sphenoid. At the angle of junction of the petrous and squamous portions are seen two canals, separated from one another by a thin plate of bone, the *processus cochleariformis*; they both lead into the tympanum, the upper one transmitting the Tensor tympani muscle, the lower one forming the bony part of the Eustachian tube.

Structure.—The squamous portion is like that of the other cranial bones: the mastoid portion, cellular; and the petrous portion, dense and hard.

Development (Fig. 36).—The temporal bone is developed by *ten* centres, exclusive of those for the internal ear and the ossicula—viz., one of the squamous portion including the zygoma, one for the tympanic plate, six for the petrous and mastoid parts, and two for the styloid process. Just before the close of foetal life the temporal bone consists of four parts: 1. The *squamo-zygomatic*, which is ossified in membrane from a single nucleus, which appears at its lower part about the second month. 2. The *tympanic plate*, an imperfect ring, in the concavity of which is a groove, the *sulcus tympanicus*, for the attachment of the circumference of the tympanic membrane. This is also ossified from a single centre, which appears about the third month. 3. The *petro-mastoid*, which is developed from six centres, which appear about the fifth or sixth month. Four of these are for the petrous portion, and are placed around the labyrinth, and two for the mastoid (Vrolik). According to Huxley, the centres are more numerous, and are disposed so as to form three portions: (1) including most of the labyrinth, with a part of the petrous and mastoid, he has named *prootic*; (2) the rest of the petrous, the *opisthotic*; and (3) the remainder of the mastoid, the *epiotic*. The petro-mastoid is ossified in cartilage. 4. The *styloid process* is also ossified in cartilage from two centres: one for the base, which appears before birth, and is termed the *tympano-hyal*; the other, comprising the rest of the process, is named the *stylo-hyal*, and does not appear until after birth. Shortly before birth the tympanic plate joins with the squamous. The petrous and mastoid join with the squamous during the first year, and the tympano-hyal portion of the styloid process about the same time. The stylo-hyal does not join the rest of the bone until after puberty, and in some skulls never becomes united. The subsequent changes in this bone are, that the tympanic plate extends outward and backward, so as to form the meatus auditorius. The extension of the tympanic plate, however, does not take place at an equal rate all round the circumference of the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, the *foramen of Huschke*: this foramen may persist throughout life. The glenoid cavity is at first extremely shallow, and looks outward as well as downward; it becomes deeper and is ultimately directed downward. Its change in direction is accounted for

FIG. 36. — Development of the temporal bone. By ten centres.

as follows: the part of the squamous temporal which supports it lies at first *below* the level of the zygoma. As, however, the base of the skull increases in width, this lower part of the squama is directed horizontally inward to contribute to the middle fossa of the skull, and its surfaces therefore come to look upward and downward. The mastoid portion is at first quite flat, and the stylo-mastoid foramen and rudimentary styloid process lie immediately behind the entrance to the auditory meatus. With the development of the air-cells the outer part of the mastoid portion grows downward and forward to form the mastoid process, and the styloid process and stylo-mastoid foramen now come to lie on the under surface. The descent of the foramen is necessarily accompanied by a corresponding lengthening of the aqueduct of Fallopius.

The downward and forward growth of the mastoid process also pushes forward the tympanic plate, so that the portion of it which formed the original floor of the meatus and containing the foramen of Huschke is ultimately found in the anterior wall. With the gradual increase in size of the petrous portion the floccular fossa or tunnel under the superior semicircular canal becomes filled up and almost obliterated.

Articulations.—With five bones—occipital, parietal, sphenoid, inferior maxillary, and malar.

Attachment of Muscles.—To fifteen: to the squamous portion, the Temporal; to the zygoma, the Masseter; to the mastoid portion, the Occipito-frontalis, Sternomastoid, Splenius capitis, Trachelo-mastoid, Digastricus, and Retrahens aurem; to the styloid process, the Stylo-pharyngeus, Stylo-hyoideus, and Stylo-glossus; and to the petrous portion, the Levator palati, Tensor tympani, Tensor palati, and Stapedius.

The Sphenoid Bone.

The **Sphenoid Bone** (σφήν, a wedge) is situated at the anterior part of the base of the skull, articulating with all the other cranial bones, which it binds firmly and solidly together. In its form it somewhat resembles a bat with its wings extended; and is divided into a central portion or body, two greater and two lesser wings extending outward on each side of the body, and two processes—the pterygoid processes—which project from it below.

FIG. 37.—Sphenoid bone. Superior surface.

The **body** is of large size, and hollowed out in its interior so as to form a mere shell of bone. It presents for examination *four* surfaces—a superior, an inferior, an anterior, and a posterior.

The Superior Surface (Fig. 37).—In front is seen a prominent spine, the

ethmoidal spine, for articulation with the cribriform plate of the ethmoid; behind this a smooth surface presenting, in the median line, a slight longitudinal eminence, with a depression on each side for lodging the olfactory lobes. This surface is bounded behind by a ridge, which forms the anterior border of a narrow, transverse groove, the *optic groove*, behind which lies the optic commissure; the ridge terminates on either side of the *optic foramen*, for the passage of the optic nerve and ophthalmic artery. Behind the optic groove is a small eminence, olive-like in shape, the *olivary process*; and still more posteriorly, a deep depression, the *pituitary fossa*, or *sella turcica*, which lodges the pituitary body. This fossa is perforated by numerous foramina, for the transmission of nutrient vessels into the substance of the bone. It is bounded in front by two small eminences, one on either side, called the *middle clinoid processes* (*κλίση*, a bed), which are sometimes connected by a spiculum of bone to the anterior clinoid processes, and behind by a square-shaped plate of bone, the *dorsum ephippii* or *dorsum sellæ*, terminating at each superior angle in a tubercle, the *posterior clinoid processes*, the size and form of which vary considerably in different individuals. These processes deepen the pituitary fossa, and serve for the attachment of prolongations from the tentorium cerebelli. The sides of the *dorsum ephippii* are notched for the passage of the sixth pair of nerves, and below present a sharp process, the *petrosal process*, which is joined to the apex of the petrous portion of the temporal bone, forming the inner boundary of the middle lacerated foramen. Behind this plate the bone presents a shallow depression, which slopes obliquely backward, and is continuous with the basilar groove of the occipital bone; it is called the *clivus*, and supports the upper part of the pons Varolii. On either side of the body is a broad groove, curved something like the italic letter *f*; it lodges the internal carotid artery and the cavernous sinus, and is called the *carotid* or *cavernous groove*. Along the outer margin of this groove, at its posterior part, is a ridge of bone in the angle between the body and greater wing, called the *lingula*. The *posterior surface*, quadrilateral

FIG. 38.—Sphenoid bone. Anterior surface.¹

in form, is joined to the basilar process of the occipital bone. During childhood these bones are separated by a layer of cartilage; but in after-life (between the eighteenth and twenty-fifth years) this becomes ossified, ossification commencing above and extending downward; and the two bones then form one piece. The *anterior surface* (Fig. 38) presents, in the middle line, a vertical ridge of bone, the

¹ In this figure, both the anterior and inferior surfaces of the body of the sphenoid bone are shown, the bone being held with the pterygoid processes almost horizontal.

ethmoidal crest, which articulates in front with the perpendicular plate of the ethmoid, forming part of the septum of the nose. On either side of it are irregular openings leading into the *sphenoidal cells* or *sinuses*. These are two large irregular cavities hollowed out of the interior of the body of the sphenoid bone, and separated from one another by a more or less complete perpendicular bony septum. Their form and size vary considerably; they are seldom symmetrical, and are often partially subdivided by irregular osseous laminae. Occasionally, they extend into the basilar process of the occipital nearly as far as the foramen magnum. The septum is seldom quite vertical, being commonly bent to one or the other side. These sinuses do not exist in children, but they increase in size as age advances. They are partially closed, in front and below, by two thin, curved plates of bone, the *sphenoidal turbinated* bones, leaving a round opening at their upper parts, by which they communicate with the upper and back part of the nose, and occasionally with the posterior ethmoidal cells or sinuses. The lateral margins of this surface present a serrated edge, which articulates with the os planum of the ethmoid, completing the posterior ethmoidal cells; the lower margin, also rough and serrated, articulates with the orbital process of the palate bone, and the upper margin with the orbital plate of the frontal bone. The *inferior surface* presents, in the middle line, a triangular spine, the *rostrum*, which is continuous with the sphenoidal crest on the anterior surface, and is received into a deep fissure between the alæ of the vomer. On each side may be seen a projecting lamina of bone, which runs horizontally inward from near the base of the pterygoid process: these plates, termed the *vaginal processes*, articulate with the edges of the vomer. Close to the root of the pterygoid process is a groove, formed into a complete canal when articulated with the sphenoidal process of the palate bone; it is called the *pterygo-palatine canal*, and transmits the pterygo-palatine vessels and pharyngeal nerve.

The **Greater Wings** are two strong processes of bone which arise from the sides of the body, and are curved in a direction upward, outward, and backward, being prolonged behind into a sharp-pointed extremity, the *spinous process* of the sphenoid. Each wing presents three surfaces and a circumference. The *superior* or *cerebral surface* (Fig. 37) forms part of the middle fossa of the skull; it is deeply concave, and presents eminences and depressions for the convolutions of the brain. At its anterior and internal part is seen a circular aperture, the *foramen rotundum*, for the transmission of the second division of the fifth nerve. Behind and external to this is a large oval foramen, the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve.¹ At the inner side of the foramen ovale a small aperture may occasionally be seen opposite the root of the pterygoid process; it is the *foramen Vesalii*, transmitting a small vein. Lastly, in the posterior angle, near to the spine of the sphenoid, is a short canal, sometimes double, the *foramen spinosum*; it transmits the middle meningeal artery. The *external surface* (Fig. 38) is convex, and divided by a transverse ridge, the *pterygoid ridge* or *infratemporal crest*, into two portions. The superior or larger, convex from above downward, concave from before backward, enters into the formation of the temporal fossa, and gives attachment to part of the Temporal muscle. The inferior portion, smaller in size and concave, enters into the formation of the zygomatic fossa, and affords attachment to the External pterygoid muscle. It presents, at its posterior part, a sharp-pointed eminence of bone, the *spinous process*, to which are connected the internal lateral ligament of the lower jaw and the Tensor palati muscle. The pterygoid ridge, dividing the temporal and zygomatic portions, gives attachment to part of the External pterygoid muscle. At its inner and anterior extremity is a triangular spine of bone which serves to increase the extent of origin of this muscle. The *anterior* or *orbital surface*, smooth and quadrilateral in form, assists in forming the outer wall of the orbit. It is bounded

¹ The small petrosal nerve sometimes passes through a special foramen between the foramen ovale and foramen spinosum.

above by a serrated edge, for articulation with the frontal bone; below, by a rounded border which enters into the formation of the sphenomaxillary fissure. Internally, it presents a sharp border, which forms the lower boundary of the sphenoidal fissure, and has projecting from about its centre a little tubercle of bone, which gives origin to one head of the External rectus muscle of the eye; and at its upper part is a notch for the transmission of a recurrent branch of the lachrymal artery; externally it presents a serrated margin for articulation with the malar bone. One or two small foramina may occasionally be seen for the passage of branches of the deep temporal arteries; they are called the *external orbital foramina*. *Circumference of the great wing* (Fig. 37), commencing from behind, that portion of the circumference from the body of the sphenoid to the spine, is serrated and articulates by its outer half with the petrous portion of the temporal bone, while the inner half forms the anterior boundary of the foramen lacerum medium, and presents the posterior aperture of the Vidian canal for the passage of the Vidian nerve and artery. In front of the spine the circumference of the great wing presents a serrated edge, bevelled at the expense of the inner table below and of the external above, which articulates with the squamous portion of the temporal bone. At the tip of the great wing a triangular portion is seen, bevelled at the expense of the internal surface, for articulation with the anterior inferior angle of the parietal bone. Internal to this is a triangular, serrated surface, for articulation with the frontal bone: this surface is continuous internally with the sharp inner edge of the orbital plate, which assists in the formation of the sphenoidal fissure, and externally with the serrated margin for articulation with the malar bone.

The **Lesser Wings** (*processes of Ingrassias*) are two thin, triangular plates of bone which arise from the upper and lateral parts of the body of the sphenoid, and, projecting transversely outward, terminate in a sharp point (Fig. 37). The superior surface of each is smooth, flat, broader internally than externally, and supports part of the frontal lobe of the brain. The inferior surface forms the back part of the roof of the orbit and the upper boundary of the sphenoidal fissure or foramen lacerum anterius. This fissure is of a triangular form, and leads from the cavity of the cranium into the orbit; it is bounded internally by the body of the sphenoid—above, by the lesser wing; below, by the internal margin of the orbital surface of the great wing—and is converted into a foramen by the articulation of this bone with the frontal. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. The anterior border of the lesser wing is serrated for articulation with the frontal bone; the posterior, smooth and rounded, is received into the fissure of Sylvius of the brain. The inner extremity of this border forms the *anterior clinoid process*. The lesser wing is connected to the side of the body by two roots, the upper thin and flat, the lower thicker, obliquely directed, and presenting on its outer side, near its junction with the body, a small tubercle, for the attachment of the common tendon of origin of three of the muscles of the eye. Between the two roots is the *optic foramen*, for the transmission of the optic nerve and ophthalmic artery.

The **Pterygoid Processes** (πτέρυξ, a wing; εἶδος, likeness), one on each side, descend perpendicularly from the point where the body and greater wing unite (Fig. 39). Each process consists of an external and an internal plate, which are joined together by their anterior borders above, but are separated below, leaving an angular cleft, the *pterygoid notch*, in which the pterygoid process or tuberosity of the palate bone is received. The two plates diverge from each other from their line of connection in front, so as to form a V-shaped fossa, the *pterygoid fossa*. The *external pterygoid plate* is broad and thin, turned a little outward, and, by its outer surface, forms part of the inner wall of the zygomatic fossa, giving attachment to the External pterygoid; its inner surface forms part

of the pterygoid fossa, and gives attachment to the Internal pterygoid. The *internal pterygoid plate* is much narrower and longer, curving outward, at its extremity, into a hook-like process of bone, the *hamular process*, around which turns the tendon of the Tensor palati muscle. The outer surface of this plate forms part of the pterygoid fossa, the inner surface forming the outer boundary of the posterior aperture of the nares. On the posterior surface of the base of the process, above the pterygoid fossa, is a small, oval, shallow depression, the *scaphoid fossa*, from which arises the Tensor palati, and above which is seen the

FIG. 39.—Sphenoid bone. Posterior surface.

posterior orifice of the Vidian canal. Below and to the inner side of the Vidian canal, on the posterior surface of the base of the internal plate, is a little prominence, which is known by the name of the *pterygoid tubercle*. The Superior constrictor of the pharynx is attached to the posterior edge of the internal plate. The anterior surface of the pterygoid process is very broad at its base, and forms the posterior wall of the spheno-maxillary fossa. It supports Meckel's ganglion. It presents, above, the anterior orifice of the Vidian canal; and below, a rough margin, which articulates with the perpendicular plate of the palate bone.

The **Sphenoidal Spongy Bones** are two thin, curved plates of bones, which exist as separate pieces until puberty, and occasionally are not joined to the sphenoid in the adult. They are situated at the anterior and inferior part of the body of the sphenoid, an aperture of variable size being left in their anterior wall, through which the sphenoidal sinuses open into the nasal fossæ. They are irregular in form and taper to a point behind, being broader and thinner in front. Their upper surface, which looks toward the cavity of the sinus, is concave; their under surface convex. Each bone articulates in front with the ethmoid, externally with the palate; its pointed posterior extremity is placed above the vomer, and is received between the root of the pterygoid process on the outer side and the rostrum of the sphenoid on the inner.¹

Development.—Up to about the eighth month of foetal life the sphenoid bone consists of two distinct parts: posterior or *post-sphenoid* part, which comprises the pituitary fossa, the greater wings, and the pterygoid processes; and an anterior or *pre-sphenoid* part, to which the anterior part of the body and lesser wings belong. It is developed by fourteen centres: eight for the posterior sphenoid division, and six for the anterior sphenoid. The eight centres for the posterior sphenoid are—one for each greater wing and external pterygoid plate, one for each internal pterygoid plate, two for the posterior part of the body, and

¹ A small portion of the sphenoidal turbinated bone sometimes enters into the formation of the inner wall of the orbit, between the os planum of the ethmoid in front, the orbital plate of the palate below, and the frontal above.—Cleland, *Roy. Soc. Trans.*, 1862.

one on each side for the lingula. The six for the anterior sphenoid are one for each lesser wing, two for the anterior part of the body, and one for each sphenoidal turbinated bone.

Post-sphenoid Division.—The first nuclei to appear are those for the greater wings (*ali-sphenoids*). They make their appearance between the foramen rotundum and foramen ovale about the eighth week, and from them the external pterygoid plates are also formed. Soon after, the nuclei for the posterior part of the body appear, one on either side of the sella turcica, and become blended together about the middle of foetal life. About the fourth month the remaining four centres appear, those for the internal pterygoid plates being ossified in membrane and becoming joined to the external pterygoid plate about the sixth month. The centres for the lingulae speedily become joined to the rest of the bone.

FIG. 40.—Plan of the development of sphenoid. By fourteen centres.

Pre-sphenoid Division.—The first nuclei to appear are those for the lesser wings (*orbito-sphenoids*). They make their appearance about the ninth week, at the outer borders of the optic foramina. A second pair of nuclei appear on the inner side of the foramina shortly after, and, becoming united, form the front part of the body of the bone. The remaining two centres for the sphenoidal turbinated bones make their appearance about the fifth month. At birth they consist of small triangular laminae, and it is not till the third year that they become hollowed out and cone-shaped. About the fourth year they become fused with the lateral masses of the ethmoid, and hence, from an embryological point of view, may be regarded as belonging to the ethmoid.

The pre-sphenoid is united to the body of the post-sphenoid about the eighth month, so that at birth the bone consists of three pieces—viz. the body in the centre, and on each side the great wings with the pterygoid processes. The lesser wings become joined to the body at about the time of birth. At the first year after birth the greater wings and body are united. From the tenth to the twelfth year the spongy bones are partially united to the sphenoid, their junction being complete by the twentieth year. Lastly, the sphenoid joins the occipital from the eighteenth to the twenty-fifth year.

Articulations.—The sphenoid articulates with *all* the bones of the cranium, and five of the face—the two malar, two palate, and vomer: the exact extent of articulation with each bone is shown in the accompanying figures.¹

Attachment of Muscles.—To eleven pairs: the Temporal, External pterygoid, Internal pterygoid, Superior constrictor, Tensor palati, Levator palpebrae, Obliquus oculi superior, Superior rectus, Internal rectus, Inferior rectus, External rectus.

The Ethmoid Bone.

The **Ethmoid** (*ἰθμός*, a sieve) is an exceedingly light, spongy bone, of a cubical form, situated at the anterior part of the base of the cranium, between the two

¹ It also sometimes articulates with the tuberosity of the superior maxilla.

orbits, at the root of the nose, and contributing to form each of these cavities. It consists of three parts: a horizontal plate, which forms part of the base of the cranium; a perpendicular plate, which forms part of the septum nasi; and two lateral masses of cells.

The **Horizontal or Cribriiform Plate** (Fig. 41) forms part of the anterior fossa of the base of the skull, and is received into the ethmoid notch of the frontal

FIG. 41.—Ethmoid bone. Outer surface of right lateral mass (enlarged).

bone between the two orbital plates. Projecting upward from the middle line of this plate is a thick, smooth, triangular process of bone, the *crista galli*, so called from its resemblance to a cock's comb. Its base joins the cribriform plate. Its posterior border, long, thin, and slightly curved, serves for the attachment of the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone, and presents two small projecting alæ, which are received into corresponding depressions in the frontal, completing the foramen cæcum behind. Its sides are smooth and sometimes bulging; in which case it is found to enclose a small sinus.¹ On each side of the crista galli the cribriform plate is narrow and deeply grooved, to support the bulb of the olfactory tract, and perforated by foramina for the passage of the olfactory nerves. These foramina are arranged in three rows: the innermost, which are the largest and least numerous, are lost in grooves on the upper part of the septum; the foramina of the outer row are continued on to the surface of the upper spongy bone. The foramina of the middle row are the smallest; they perforate the bone and transmit nerves to the roof of the nose. At the front part of the cribriform plate, on each side of the crista galli, is a small fissure, which transmits the nasal branch of the ophthalmic nerve; and at its posterior part a triangular notch, which receives the ethmoidal spine of the sphenoid.

The **Perpendicular Plate** (Fig. 42) is a thin, flattened lamella of bone, which descends from the under surface of the cribriform plate, and assists in forming the septum of the nose. It is much thinner in the middle than at the circumference, and is generally deflected a little to one side. Its anterior border articulates with the nasal spine of the frontal bone and crest of the nasal bones. Its posterior border, divided into two parts, articulates by its upper half with the sphenoidal crest of the sphenoid, by its lower half with the vomer. The inferior border serves for the attachment of the triangular cartilage of the nose. On each side of the perpendicular plate numerous grooves and canals are seen, leading from foramina on the cribriform plate; they lodge filaments of the olfactory nerves.

The **Lateral Masses** of the ethmoid consist of a number of thin-walled cellular cavities, the *ethmoidal cells*, interposed between two vertical plates of bone, the outer one of which forms part of the orbit, and the inner one part of the nasal fossa of the corresponding side. In the disarticulated bone many of these cells appear to be broken; but when the bones are articulated they are closed in at every part, except where they open into the nasal fossæ. The upper surface of each lateral mass presents a number of apparently half-broken cel-

¹ Sir George Humphry states that the crista galli is commonly inclined to one side, usually the opposite to that toward which the lower part of the perpendicular plate is bent.—*The Human Skeleton*, 1858, p. 277.

lular spaces; these are closed in when articulated by the edges of the ethmoidal notch of the frontal bone. Crossing this surface are two grooves on each side, converted into canals by articulation with the frontal; they are the *anterior* and *posterior ethmoidal* canals, and open on the inner wall of the orbit. The posterior surface also presents large, irregular cellular cavities, which

are closed in by articulation with the sphenoidal turbinated bones and orbital process of the palate. The cells at the anterior surface are completed by the lachrymal bone and nasal process of the superior maxillary, and those below also by the superior maxillary. The outer surface of each lateral mass is formed of a thin, smooth, oblong plate of bone, called the *os planum*; it forms part of the inner wall of the orbit, and articulates, above, with the orbital plate of the frontal; below, with the superior maxillary.

FIG. 42.—Perpendicular plate of ethmoid (enlarged), shown by removing the right lateral mass.

lary; in front, with the lachrymal; and behind, with the sphenoid and orbital process of the palate.

From the inferior part of each lateral mass, immediately beneath the *os planum*, there projects downward and backward an irregular lamina of bone, called the *unciform process*, from its hook-like form: it serves to close in the upper part of the orifice of the antrum, and articulates with the ethmoidal process of the inferior turbinated bone. It is often broken in disarticulating the bones.

The inner surface of each lateral mass forms part of the outer wall of the nasal fossa of the corresponding side. It is formed of a thin lamella of bone, which descends from the under surface of the cribriform plate, and terminates below in a free, convoluted margin, the *middle turbinated bone*. The whole of this surface is rough and marked above by numerous grooves, which run nearly vertically downward from the cribriform plate; they lodge branches of the olfactory nerve, which are distributed on the mucous membrane covering the bone. The back part of this surface is subdivided by a narrow oblique fissure, the *superior meatus* of the nose, bounded above by a thin, curved plate of bone, the *superior turbinated bone*. By means of an orifice at the upper part of this fissure the posterior ethmoidal cells open into the nose. Below, and in front of the superior meatus, is seen the convex surface of the middle turbinated bone. It extends along the whole length of the inner surface of each lateral mass; its lower margin is free and thick, and its concavity, directed outward, assists in forming the middle meatus. It is by a large orifice at the upper and front part of the middle meatus that the anterior ethmoidal cells, and through them the frontal sinuses, communicate with the nose by means of a funnel-shaped canal, the *infundibulum*.

FIG. 43.—Ethmoid bone. Inner surface of right lateral mass (enlarged).

The cellular cavities of each lateral mass, thus walled in by the os planum on the outer side and by the other bones already mentioned, are divided by a thin transverse bony partition into two sets, which do not communicate with each other; they are termed the *anterior* and *posterior ethmoidal cells* or *sinuses*. The former, more numerous, communicate with the frontal sinuses above and the middle meatus below by means of a long, flexuous canal, the *infundibulum*; the posterior, less numerous, open into the superior meatus, and communicate (occasionally) with the sphenoidal sinuses.

Development.—By *three* centres: one for the perpendicular lamella, and one for each lateral mass.

The lateral masses are first developed, ossific granules making their appearance in the os planum between the fourth and fifth months of foetal life, and extending into the spongy bones. At birth the bone consists of the two lateral masses, which are small and ill-developed. During the first year after birth the perpendicular plate and crista galli begin to ossify, from a single nucleus, and become joined to the lateral masses about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the lateral masses. The formation of the ethmoidal cells, which completes the bone, does not commence until about the fourth or fifth year.

Articulations.—With fifteen bones: the sphenoid, two sphenoidal turbinated, the frontal, and eleven of the face—the two nasal, two superior maxillary, two lachrymal, two palate, two inferior turbinated, and the vomer. No muscles are attached to this bone.

DEVELOPMENT OF THE CRANIUM.

The early stages of the development of the cranium have already been described. We have seen that it is formed from a layer of mesoblast, derived from the protovertebral plates of the trunk, which is spread over the whole surface of the rudimentary brain. That portion of this layer from which the bones of the skull are to be developed consists of a thin, membranous capsule.

Ossification commences in the roof, and is preceded by the deposition of a membranous blastema upon the surface of the cerebral capsule, in which the ossifying process extends, the primitive membranous capsule becoming the internal periosteum, and being ultimately blended with the dura mater. The ossification of the bones of the base takes place for the most part in cartilage, and although the bones of the vertex of the skull appear before those at the base, and make considerable progress in their growth, at birth ossification is more advanced in the base, this portion of the skull forming a solid, immovable groundwork.

The Fontanelles.

Before birth the bones at the vertex and side of the skull are separated from each other by membranous intervals in which bone is deficient. These intervals are principally found at the four angles of the parietal bones. Hence there are six fontanelles. Their formation is due to

FIG. 44.—Skull at birth, showing the anterior and posterior fontanelles.

FIG. 45.—The lateral fontanelles.

the wave of ossification being circular and the bones quadrilateral; the ossific matter first meets at the margins of the bones, at the points nearest to their centres of ossification, and vacuities

or spaces are left at the angles, which are called *fontanelles*, so named from the pulsations of the brain, which are perceptible at the anterior fontanelle, were likened to the rising of water in a fountain. The anterior fontanelle is the largest; it is lozenge-shaped, and corresponds to the junction of the sagittal and coronal sutures; the posterior fontanelle, of smaller size, is triangular, and is situated at the junction of the sagittal and lambdoid sutures; the remaining ones are situated at the inferior angles of each parietal bone. The latter are closed soon after birth; the two at the two superior angles remain open longer; the posterior being closed in a few months after birth; the anterior remaining open until the first or second year. These spaces are gradually filled in by an extension of the ossifying process or by the development of a Wormian bone. Sometimes the anterior fontanelle remains open beyond two years, and is occasionally persistent throughout life.

Supernumerary or Wormian¹ Bones.

In addition to the constant centres of ossification of the skull, additional ones are occasionally found in the course of the sutures. These form irregular, isolated bones, interposed between the cranial bones, and have been termed *Wormian bones* or *ossa triquetra*. They are most frequently found in the course of the lambdoid suture, but occasionally also occupy the situation of the fontanelles, especially the posterior and, more rarely, the anterior. Frequently one is found between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid, the *pterion ossicle* (Fig. 45). They have a great tendency to be symmetrical on the two sides of the skull, and they vary much in size, being in some cases not larger than a pin's head, and confined to the outer table; in other cases so large that one pair of these bones may form the whole of the occipital bone above the superior curved lines, as described by Bécord and Ward. Their number is generally limited to two or three, but more than a hundred have been found in the skull of an adult hydrocephalic skeleton. In their development, structure, and mode of articulation they resemble the other cranial bones.

Congenital Fissures and Gaps.

An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margins toward the centre of the bone, but the gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

BONES OF THE FACE.

The Facial Bones are fourteen in number—viz. the

Two Nasal.	Two Palate.
Two Superior Maxillary.	Two Inferior Turbinated.
Two Lachrymal.	Vomer.
Two Malar.	Inferior Maxillary.

“Of these, the upper and lower jaws are the fundamental bones for mastication, and the others are accessories; for the chief function of the facial bones is to provide an apparatus for mastication, while subsidiary functions are to provide for the sense-organs (eye, nose, tongue) and a vestibule to the respiratory and vocal organs. Hence the variations in the shape of the face in man and the lower animals depend chiefly on the question of the character of their food and their mode of obtaining it.”²

The Nasal Bone.

The **Nasal** (*nasus*, the nose) are two small oblong bones, varying in size and form in different individuals; they are placed side by side at the middle and upper part of the face, forming, by their junction, “the bridge” of the nose (Fig. 46). Each bone presents for examination two surfaces and four borders. The *outer* surface is concave from above downward, convex from side to side; it is covered by the *Pyramidalis* and *Compressor nasi* muscles, and gives attachment at its upper part to a few fibres of the *Occipito-frontalis* muscle (Theile). It is marked by numerous small arterial furrows, and perforated about its centre by a foramen, sometimes double, for the transmission of a small vein. The *inner* surface is concave from side to side, convex from above downward; in which direction

¹ Wormius, a physician in Copenhagen, is said to have given the first detailed description of these bones.

² W. W. Keen, American edition p. 185.

it is traversed by a longitudinal groove (sometimes a canal), for the passage of a branch of the nasal nerve. The *superior* border is narrow, thick, and serrated, for articulation with the nasal notch of the frontal bone. The *inferior*

FIG. 46.—Nasal and lachrymal bone *in situ*.

border is broad, thin, sharp, inclined obliquely downward, outward, and backward, and serves for the attachment of the lateral cartilage of the nose. This border presents, about its middle, a notch, through which passes the branch of the nasal nerve above referred to, and is prolonged at its inner extremity into a sharp

spine, which, when articulated with the opposite bone, forms the *nasal angle*. The *external* border is serrated, bevelled at the expense of the internal surface above and of the external surface below, to articulate with the nasal process of the superior maxillary. The *internal* border, thicker above than below, articulates with its fellow of the opposite side, and is prolonged behind into a vertical crest which forms part of the

FIG. 47.—Right nasal bone.

FIG. 48.—Left nasal bone.

septum of the nose; this crest articulates above downward with the nasal spine of the frontal above, and the perpendicular plate of the ethmoid, and the triangular septal cartilage of the nose.

Development.—By *one* centre for each bone, which appears about the eighth week.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the opposite nasal and the superior maxillary.

Attachment of Muscles.—A few fibres of the Occipito-frontalis muscle.

The Superior Maxillary Bones or Maxillæ.

The **Superior Maxillary** (*maxilla*, the jaw-bone) are the most important bones of the face from a surgical point of view, on account of the number of diseases to which some of their parts are liable. Their careful examination becomes, therefore, a matter of considerable interest. They are the largest bones of the face, excepting the lower jaw, and form, by their union, the whole of the upper jaw. Each bone assists in the formation of three cavities, the roof of the mouth, the floor and outer wall of the nasal fossæ, and the floor of the orbit, and also enters into the formation of two fossæ, the zygomatic and speno-maxillary, and two fissures, the speno-maxillary and pterygo-maxillary.

The bone presents for examination a body and four processes—malar, nasal, alveolar, and palate.

The **body** is somewhat cuboid, and is hollowed out in its interior to form a large cavity, the *antrum of Highmore*. Its surfaces are four—an external or facial, a posterior or zygomatic, a superior or orbital, and an internal or nasal.

The **external or facial surface** (Fig. 49) is directed forward and outward. It presents at its lower part a series of eminences corresponding to the position of the teeth. Just above those for the incisor teeth is a depression, the *incisive* or *myrtiform fossa*, which gives origin to the Depressor alæ nasi; and below it to the alveolar border is attached a slip of the Orbicularis oris. Above and a little external to it the Compressor nasi arises. More external is another depression, the *canine fossa*, larger and deeper than the incisive fossa, from which

Outer Surface.

FIG. 49.—Left superior maxillary bone. Outer surface.

it is separated by a vertical ridge, the *canine eminence*, corresponding to the socket of the canine tooth. The canine fossa gives origin to the Levator anguli oris. Above the canine fossa is the *infraorbital foramen*, the termination of the infraorbital canal; it transmits the infraorbital vessels and nerve. Sometimes the infraorbital canal opens by two, very rarely by three, orifices on the face. Above the infraorbital foramen is the margin of the orbit, which affords partial attachment to the Levator labii superioris proprius. To the sharp margin of bone

which bounds this surface in front and separates it from the internal surface is attached the Dilator naris posterior.

The **posterior or zygomatic surface** is convex, directed backward and outward, and forms part of the zygomatic fossa. It is separated from the facial surface by a strong ridge of bone, which extends upward from the socket of the second molar tooth. It presents about its centre several apertures leading to canals in the substance of the bone; they are termed the *posterior dental canals*, and transmit the posterior dental vessels and nerves. At the lower part of this surface is a rounded eminence, the *maxillary tuberosity*, especially prominent after the growth of the wisdom-tooth, rough on its inner side for articulation with the tuberosity of the palate bone, and sometimes with the external pterygoid plate. It gives attachment to a few fibres of origin of the Internal pterygoid muscle. Immediately above this is a smooth surface, which forms the anterior boundary of the speno-maxillary fossa; it presents a groove which, running obliquely downward, is converted into a canal by articulation with the palate-bone, forming the *posterior palatine canal*.

The **superior or orbital surface** is thin, smooth, triangular, and forms part of the floor of the orbit. It is bounded internally by an irregular margin which in front presents a notch, the *lachrymal notch*, which receives the lachrymal bone; in the middle articulates with the os planum of the ethmoid, and behind with the orbital process of the palate bone; bounded externally by a smooth, rounded edge which enters into the formation of the speno-maxillary fissure, and which sometimes articulates at its anterior extremity with the orbital plate of the sphenoid; bounded in front by part of the circumference of the orbit, which is continuous on the inner side with the nasal, on the outer side with the malar, process. Along the middle line of the orbital surface is a deep groove, the *infraorbital*, for the passage of the infraorbital vessels and nerve. The groove commences at the middle of the outer border of this surface, and, passing forward, terminates in a canal, which subdivides into two branches. One of the canals, the *infraorbital*, opens

FIG. 50.—Left superior maxillary bone. Internal surface.

just below the margin of the orbit; the other, which is smaller, runs downward in the substance of the anterior wall of the antrum; it is called the *anterior dental canal*, and transmits the anterior dental vessels and nerve to the front teeth of

the upper jaw. From the back part of the infraorbital canal a second small canal is sometimes given off, which runs downward in the outer wall of the antrum, and conveys the middle dental nerve to the bicuspid teeth. Occasionally this canal is derived from the anterior dental. At the inner and fore part of the orbital surface, just external to the lachrymal groove for the nasal duct, is a depression which gives origin to the Inferior oblique muscle of the eye.

The **internal surface** (Fig. 50) is unequally divided into two parts by a horizontal projection of bone, the *palate process*: the portion above the palate process forms part of the outer wall of the nasal fossæ; that below it forms part of the cavity of the mouth. The superior division of this surface presents a large, irregular opening leading into the *antrum of Highmore*. At the upper border of this aperture are numerous broken cellular cavities, which in the articulated skull are closed in by the ethmoid and lachrymal bones. Below the aperture is a smooth concavity which forms part of the inferior meatus of the nasal fossæ, and behind it is a rough surface which articulates with the perpendicular plate of the palate bone, traversed by a groove which, commencing near the middle of the posterior border, runs obliquely downward and forward, and forms, when completed by its articulation with the palate bone, the *posterior palatine canal*. In front of the opening of the antrum is a deep groove, converted into a canal by the lachrymal and inferior turbinated bones. It is called the *lachrymal groove*, and lodges the nasal duct. More anteriorly is a well-marked rough ridge, the *inferior turbinated crest*, for articulation with the inferior turbinated bone. The shallow concavity above this ridge forms part of the middle meatus of the nose, while that below it forms part of the inferior meatus. The portion of this surface below the palate process is concave, rough and uneven, and perforated by numerous small foramina for the passage of nutrient vessels. It enters into the formation of the roof of the mouth.

The **Antrum of Highmore**, or **Maxillary Sinus**, is a large, pyramidal cavity hollowed out of the body of the maxillary bone: its apex, directed outward, is formed by the malar process; its base, by the outer wall of the nose. Its walls are everywhere exceedingly thin, and correspond to the orbital, facial, and zygomatic surfaces of the body of the bone. Its inner wall, or base, presents, in the disarticulated bone, a large, irregular aperture, which communicates with the nasal fossa. The margins of this aperture are thin and ragged, and the aperture itself is much contracted by its articulation with the ethmoid above, the inferior turbinated below, and the palate bone behind.¹ In the articulated skull this cavity communicates with the middle meatus of the nasal fossæ, generally by two small apertures left between the above-mentioned bones. In the recent state usually only one small opening exists, near the upper part of the cavity, sufficiently large to admit the end of a probe, the other being closed by the lining membrane of the sinus.

Crossing the cavity of the antrum are often seen several projecting laminæ of bone, similar to those seen in the sinuses of the cranium; and on its posterior wall are the *posterior dental canals*, transmitting the posterior dental vessels and nerves to the teeth. Projecting into the floor are several conical processes, corresponding to the roots of the first and second molar teeth;² in some cases the floor is perforated by the teeth in this situation.

It is from the extreme thinness of the walls of this cavity that we are enabled to explain how a tumor growing from the antrum encroaches upon the adjacent parts, pushing up the floor of the orbit, and displacing the eyeball, projecting inward into the nose, protruding forward on to the cheek, and making its way backward into the zygomatic fossa and downward into the mouth.

The **Malar Process** is a rough, triangular eminence, situated at the angle of

¹ In some cases, at any rate, the lachrymal bone encroaches slightly on the anterior superior portion of the opening, and assists in forming the inner wall of the antrum.

² The number of teeth whose fangs are in relation with the floor of the antrum is variable. The antrum "may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the *dens sapientie*." (See Mr. Salter on Abscess of the Antrum, in a *System of Surgery*, edited by T. Holmes, 2d ed. vol. iv. p. 356.)

separation of the facial from the zygomatic surface. In front it is concave, forming part of the facial surface; behind it is also concave, and forms part of the zygomatic fossa; above it is rough and serrated for articulation with the malar bone; whilst below a prominent ridge marks the division between the facial and zygomatic surfaces. A small part of the Masseter muscle arises from this process.

The **Nasal Process** is a strong, triangular plate of bone, which projects upward, inward, and backward by the side of the nose, forming part of its lateral boundary. Its *external* surface is concave, smooth, perforated by numerous foramina, and gives attachment to the Levator labii superioris alæque nasi, the Orbicularis palpebrarum, and Tendo oculi. Its *internal* surface forms part of the outer wall of the nasal fossæ: at its upper part it presents a rough, uneven surface, which articulates with the ethmoid bone, closing in the anterior ethmoidal cells; below this is a transverse ridge, the *superior turbinated crest*, for articulation with the middle turbinated bone of the ethmoid, bounded below by a shallow smooth concavity which forms part of the middle meatus; below this again is the inferior turbinated crest (already described), where the process joins the body of the bone. Its upper border articulates with the frontal bone. The *anterior* border of the nasal process is thin, directed obliquely downward and forward, and presents a serrated edge for articulation with the nasal bone; its *posterior* border is thick, and hollowed into a groove, the *lachrymal groove*, for the nasal duct: of the two margins of this groove, the inner one articulates with the lachrymal bone, the outer one forms part of the circumference of the orbit. Just where the latter joins the orbital surface is a small tubercle, the *lachrymal tubercle*; this serves as a guide to the position of the lachrymal sac in the operation for fistula lachrymalis. The lachrymal groove in the articulated skull is converted into a canal by the lachrymal bone and lachrymal process of the inferior turbinated; it is directed downward, and a little backward and outward, is about the diameter of a goose-quill, slightly

FIG. 51.—The palate and alveolar arch.

narrower in the middle than at either extremity, and terminates below in the inferior meatus. It lodges the nasal duct.

The **Alveolar Process** is the thickest and most spongy part of the bone, broader behind than in front, and excavated into deep cavities for the reception of the teeth.

These cavities are eight in number, and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and subdivided into minor cavities; those for the incisors are single, but deep and narrow. The Buccinator muscle arises from the outer surface of this process, as far forward as the first molar tooth.

The **Palate Process**, thick and strong, projects horizontally inward from the inner surface of the bone. It is much thicker in front than behind, and forms a considerable part of the floor of the nostril and the roof of the mouth.

Its *inferior* surface (Fig. 51) is concave, rough and uneven, and forms part of the roof of the mouth. This surface is perforated by numerous foramina for the passage of the nutrient vessels, channelled at the back part of its alveolar border by a longitudinal groove, sometimes a canal, for the transmission of the posterior palatine vessels, and the anterior and external palatine nerves from Meckel's ganglion, and presents little depressions for the lodgement of the palatine glands. When the two superior maxillary bones are articulated together, a large orifice may be seen in the middle line, immediately behind the incisor teeth. This is the *anterior palatine canal* or *fossa*. On examining the bottom of this fossa four canals are seen: two branch off laterally to the right and left nasal fossæ, and two, one in front and one behind, lie in the middle line. The former pair of these canals are named the *foramina of Stenson*, and through them passes the anterior or terminal branch of the descending or posterior palatine arteries, which ascend from the mouth to the nasal fossæ. The canals in the middle line are termed the *foramina of Scarpa*, and transmit the naso-palatine nerves, the left passing through the anterior, and the right through the posterior, canal. On the palatal surface of the process a delicate linear suture may sometimes be seen extending from the anterior palatine fossa to the interval between the lateral incisor and the canine tooth. This marks out the intermaxillary or incisive bone, which in some animals exists permanently as a separate piece. It includes the whole thickness of the alveolus, the corresponding part of the floor of the nose, and the anterior nasal spine, and contains the sockets of the incisor teeth. The *upper* surface is concave from side to side, smooth, and forms part of the floor of the nose. It presents the upper orifices of the foramina of Stenson and Scarpa, the former being on each side of the middle line, the latter being situated in the intermaxillary suture, and therefore not visible unless the two bones are placed in apposition. The *outer* border of the palate process is incorporated with the rest of the bone. The *inner* border is thicker in front than behind, and is raised above into a ridge, the *nasal crest*, which, with the corresponding ridge in the opposite bone, forms a groove for the reception of the vomer. In front this crest rises to a considerable height, and this portion is named the *incisor crest*. The *anterior* margin is bounded by the thin, concave border of the opening of the nose, prolonged forward internally into a sharp process, forming, with a similar process of the opposite bone, the *anterior nasal spine*. The *posterior* border is serrated for articulation with the horizontal plate of the palate bone.

Development.—This bone commences to ossify at a very early period, and ossification proceeds in it with great rapidity, so that it is difficult to ascertain with certainty its precise number of centres. It appears, however, probable that it is ossified from four centres, which are deposited in membrane. 1. One which forms that portion of the body of the bone which lies internal to the infra-orbital canal, including the floor of the orbit, the outer wall of the nasal fossa, and the nasal process; 2. A second which gives origin to that portion of the bone which lies external to the infra-orbital canal

Anterior Surface.

Inferior Surface.

FIG. 52.—Development of superior maxillary bone. At birth.

and the malar process; 3. A third from which is developed the palatine process posterior to Stenson's canal and the adjoining part of the nasal wall; 4. And a fourth for the front part of the alveolus which carries the incisor teeth and corresponds to the pre-maxillary bone of the lower animals. These centres appear about the eighth week, and by the tenth week the three first-named centres have become fused together and the bone consists of two portions, one the maxilla proper, and the other the pre-maxillary portion. The suture between these two portions on the palate persists till middle life, but is not to be seen on the facial surface. This is believed by Callender to be due to the fact that the front wall of the sockets of the incisive teeth is not formed by the pre-maxillary bone, but by an outgrowth from the facial part of the superior maxilla. The antrum appears as a shallow groove on the inner surface of the bone at an earlier period than any of the other nasal sinuses, its development commencing about the fourth month of foetal life. The sockets for the teeth are formed by the growing downward of two plates from the dental groove, which subsequently becomes divided by partitions jutting across from the one to the other.

Articulations.—With *nine* bones: two of the cranium, the frontal and ethmoid, and seven of the face—viz. the nasal, malar, lachrymal, inferior turbinated, palate, vomer, and its fellow of the opposite side. Sometimes it articulates with the orbital plate of the sphenoid, and sometimes with its external pterygoid plate.

Attachment of Muscles.—To twelve: the Orbicularis palpebrarum, Obliquus oculi inferior, Levator labii superioris alæque nasi, Levator labii superioris proprius, Levator anguli oris, Compressor nasi, Depressor alæ nasi, Dilator naris posterior, Masseter, Buccinator, Internal pterygoid, and Orbicularis oris.

CHANGES PRODUCED IN THE UPPER JAW BY AGE.

At birth and during infancy the diameter of the bone is greater in an antero-posterior than in a vertical direction. Its nasal process is long, its orbital surface large, and its tuberosity well marked. In the adult the vertical diameter is the greater, owing to the development of the alveolar process and the increase in size of the antrum. In old age the bone approaches again in character to the infantile condition: its height is diminished, and after the loss of the teeth the alveolar process is absorbed, and the lower part of the bone contracted and diminished in thickness.

The Lachrymal Bones.

The **Lachrymal** (*lachryma*, a tear) are the smallest and most fragile bones of the face. They are situated at the front part of the inner wall of the orbit (Fig. 46), and resemble somewhat in form, thinness, and size a finger-nail; hence they are termed the *ossa unguis*. Each bone presents for examination two surfaces and four borders.

The **external** or orbital surface (Fig. 53) is divided by a vertical ridge, the *lachrymal crest*, into two parts. The portion of bone in front of this ridge presents a smooth, concave, longitudinal groove, the free margin of which unites with the nasal process of the superior maxillary bone, completing the lachrymal groove. The upper part of this groove lodges the lachrymal sac; the lower part lodges the nasal duct. The portion of bone behind the ridge is smooth, slightly concave, and forms part of the inner wall of the orbit. The ridge, with a part of the orbital surface immediately behind it, affords attachment to the Tensor tarsi muscle: it terminates below in a small, hook-like projection, the *hamular process*, which articulates with the lachrymal tubercle of the superior maxillary bone, and completes the upper orifice of the lachrymal groove. It sometimes exists as a separate piece, which is then called the *lesser lachrymal bone*. The **internal** or nasal surface presents a depressed furrow, corresponding to the ridge on its outer surface. The surface of bone in front of this forms part of

FIG. 53.—Left lachrymal bone. External surface. (Slightly enlarged.)

the middle meatus, and that behind it articulates with the ethmoid bone, filling in the anterior ethmoidal cells. Of the *four borders*, the *anterior* is the longest, and articulates with the nasal process of the superior maxillary bone. The *posterior*, thin and uneven, articulates with the os planum of the ethmoid. The *superior*, the shortest and thickest, articulates with the internal angular process of the frontal bone. The *inferior* is divided by the lower edge of the vertical crest into two parts; the posterior part articulates with the orbital plate of the superior maxillary bone; the anterior portion is prolonged downward into a pointed process, which articulates with the lachrymal process of the inferior turbinated bone and assists in the formation of the lachrymal groove.

Development.—By a single centre, which makes its appearance soon after ossification of the vertebræ has commenced.

Articulations.—With four bones: two of the cranium, the frontal and ethmoid, and two of the face, the superior maxillary and the inferior turbinated.

Attachment of Muscles.—To one muscle, the Tensor tarsi.

The Malar Bones.

The **Malar** (*mala*, the cheek) are two small, quadrangular bones, situated at the upper and outer part of the face: they form the prominence of the cheek, part of the outer wall and floor of the orbit, and part of the temporal and zygomatic fossæ (Fig. 54). Each bone presents for examination an external and an internal surface; four processes, the frontal, orbital, maxillary, and zygomatic; and four borders. The **external surface** (Fig. 55) is smooth, convex, perforated near its

FIG. 54.—Malar bone in situ.

centre by one or two small apertures, the *malar foramina*, for the passage of nerves and vessels, covered by the *Orbicularis palpebrarum* muscle, and affords attachment to the *Zygomaticus major* and *minor* muscles.

The **internal surface** (Fig. 56), directed backward and inward, is concave, presenting internally a rough, triangular surface, for articulation with the superior maxillary bone: and externally, a smooth concave surface, which above forms the anterior boundary of the temporal fossa, and below, where it is wider, forms part of the zygomatic fossa. This surface presents, a little above its centre, the aperture of one or two malar canals, and affords attachment to a portion of the

Masseter muscle at its lower part. Of the four processes, the **frontal** is thick and serrated, and articulates with the external angular process of the frontal bone. To its orbital margin is attached the external tarsal ligament. The **orbital** process is a thick and strong plate, which projects backward from the orbital margin of the bone. Its *supero-internal* surface, smooth and concave, forms, by its junction with the orbital surface of the superior maxillary bone and with the great wing of the sphenoid, part of the floor and

FIG. 55.—Left malar bone. Outer surface.

FIG. 56.—Left malar bone. Inner surface.

outer wall of the orbit. Its *infero-external* surface, smooth and convex, forms part of the zygomatic and temporal fossæ. Its *anterior* margin is smooth and rounded, forming part of the circumference of the orbit. Its *superior* margin, rough and directed horizontally, articulates with the frontal bone behind the external angular process. Its *posterior* margin is rough, and serrated for articulation with the sphenoid; *internally* it is also serrated for articulation with the orbital surface of the superior maxillary. At the angle of junction of the sphenoidal and maxillary portions a short, rounded, non-articular margin is generally seen; this forms the anterior boundary of the speno-maxillary fissure: occasionally, no such non-articular margin exists, the fissure being completed by the direct junction of the maxillary and sphenoid bones or by the interposition of a small Wormian bone in the angular interval between them. On the *upper* surface of the orbital process are seen the orifices of one or two temporo-malar canals; one of these usually opens on the posterior surface, the other (occasionally two) on the facial surface: they transmit filaments (temporo-malar) of the orbital branch of the superior maxillary nerve. The **maxillary** process is a rough, triangular surface which articulates with the superior maxillary bone. The **zygomatic** process, long, narrow, and serrated, articulates with the zygomatic process of the temporal bone. Of the **four borders**, the *antero-superior* or *orbital* is smooth, arched, and forms a considerable part of the circumference of the orbit. The *antero-inferior* or *maxillary* border is rough, and bevelled at the expense of its inner table, to articulate with the superior maxillary bone; affording attachment by its margin to the Levator labii superioris proprius, just at its point of junction with the superior maxillary. The *postero-superior* or *temporal* border, curved like an italic letter *f*, is continuous above with the commencement of the temporal ridge; below, with the upper border of the zygomatic arch: it affords attachment to the temporal fascia. The *postero-inferior* or *zygomatic* border is continuous with the lower border of the zygomatic arch, affording attachment by its rough edge to the Masseter muscle.

Development.—The malar bone ossifies generally from three centres, which appear about the eighth week—one for the zygomatic and two for the orbital portion—and fuse about the fifth month of foetal life. The bone is sometimes,

after birth, seen to be divided by a horizontal suture into an upper and larger and a lower and smaller division. In some quadrumana the malar bone consists of two parts, an orbital and a malar, which are ossified by separate centres.

Articulations.—With four bones: three of the cranium, frontal, sphenoid, and temporal; and one of the face, the superior maxillary.

Attachment of Muscles.—To four: The Levator labii superioris proprius, Zygomaticus major and minor, and Masseter.

The Palate Bones.

The **Palate Bones** (*palatum*, the palate) are situated at the back part of the nasal fossæ: they are wedged in between the superior maxillary bones and the pterygoid processes of the sphenoid (Fig. 57). Each bone assists in the for-

FIG. 57.—Palate bone in situ.

mation of three cavities: the floor and outer wall of the nose, the roof of the mouth, and the floor of the orbit, and enters into the formation of two fossæ, the spheno-maxillary and pterygoid; and one fissure, the spheno-maxillary. In form the palate bone somewhat resembles the letter L, and may be divided into an inferior or horizontal plate and a superior or vertical plate.

The **Horizontal Plate** is of a quadrilateral form, and presents two surfaces and four borders. The *superior* surface, concave from side to side, forms the back part of the floor of the nose. The *inferior* surface, slightly concave and rough, forms the back part of the hard palate. At its posterior part may be seen a transverse ridge, more or less marked, for the attachment of part of the aponeurosis of the Tensor palati muscle. At the outer extremity of this ridge is a deep groove converted into a canal by its articulation with the tuberosity of the superior maxillary bone, and forming the *posterior palatine canal*. Near this groove the orifices of one or two small canals, *accessory posterior palatine*, may be seen. The *anterior* border is serrated, bevelled at the expense of its inferior surface, and articulates with the palate process of the superior maxillary bone. The *posterior* border is concave, free, and serves for the attachment of the soft palate. Its inner extremity is sharp and pointed, and, when united with the opposite bone, forms a projecting process, the *posterior nasal spine*, for the attachment of the Azygos uvulæ muscle. The *external* border is united with the lower part of the perpen-

dicular plate almost at right angles. The *internal* border, the thickest, is serrated for articulation with its fellow of the opposite side; its superior edge is raised into a ridge, which, united with the opposite bone, forms a crest in which the vomer is received.

The **Vertical Plate** (Fig. 58) is thin, of an oblong form, and directed upward and a little inward. It presents two surfaces, an external and an internal, and four borders.

The *internal surface* presents at its lower part a broad, shallow depression, which forms part of the inferior meatus of the nose. Immediately above this

FIG. 58.—Left palate bone. Internal view. (Enlarged.)

is a well-marked horizontal ridge, the *inferior turbinated crest*, for articulation with the inferior turbinated bone; above this, a second broad, shallow depression, which forms part of the middle meatus, surmounted above by a horizontal ridge less prominent than the inferior, the *superior turbinated crest*, for articulation with the middle turbinated bone. Above the superior turbinated crest is a narrow, horizontal groove, which forms part of the superior meatus.

The *external surface* is rough and irregular throughout the greater part of its extent, for articulation with the inner surface of the su-

perior maxillary bone, its upper and back part being smooth where it enters into the formation of the spheno-maxillary fossa; it is also smooth in front, where it covers the orifice of the antrum. Toward the back part of this surface is a deep groove, converted into a canal, the *posterior palatine*, by its articulation with the superior maxillary bone. It transmits the posterior or descending palatine vessels and one of the descending palatine branches from Meckel's ganglion.

The *anterior border* is thin, irregular, and presents, opposite the inferior turbinated crest, a pointed, projecting lamina, the *maxillary process*, which is directed forward, and closes in the lower and back part of the opening of the antrum. The *posterior border* (Fig. 59) presents a deep groove, the edges of which are serrated for articulation with the pterygoid process of the sphenoid. At the lower part of this border is seen a pyramidal process of bone, the *pterygoid process* or tuberosity of the palate, which is received into the angular interval between the two pterygoid plates of the sphenoid at their inferior extremity. This process presents at its back part a median groove and two lateral surfaces. The groove is smooth, and forms part

FIG. 59.—Left palate bone. Posterior view. (Enlarged.)

The groove is smooth, and forms part

of the pterygoid fossa, affording attachment to the Internal pterygoid muscle; whilst the lateral surfaces are rough and uneven, for articulation with the anterior border of each pterygoid plate. A few fibres of the Superior constrictor arise from the tuberosity of the palate bone. The base of this process, continuous with the horizontal portion of the bone, presents the apertures of the *accessory descending palatine canals*, through which pass the two smaller descending branches of Meckel's ganglion; whilst its outer surface is rough for articulation with the inner surface of the body of the superior maxillary bone.

The *superior* border of the vertical plate presents two well-marked processes separated by an intervening notch or foramen. The anterior, or larger, is called the *orbital process*; the posterior, the *sphenoidal*.

The **Orbital Process**, directed upward and outward, is placed on a higher level than the sphenoidal. It presents five surfaces, which enclose a hollow cellular cavity, and is connected to the perpendicular plate by a narrow, constricted neck. Of these five surfaces, three are articular, two non-articular or free surfaces. The three articular are the *anterior* or *maxillary* surface, which is directed forward, outward, and downward, is of an oblong form, and rough for articulation with the superior maxillary bone. The *posterior* or *sphenoidal* surface is directed backward, upward, and inward. It ordinarily presents a small, open cell, which communicates with the sphenoidal cells, and the margins of which are serrated for articulation with the vertical part of the sphenoidal turbinated bone. The *internal* or *ethmoidal* surface is directed inward, upward, and forward, and articulates with the lateral mass of the ethmoid bone. In some cases the cellular cavity above mentioned opens on this surface of the bone; it then communicates with the posterior ethmoidal cells. More rarely it opens on both surfaces, and then communicates both with the posterior ethmoidal and the sphenoidal cells. The non-articular or free surfaces are the *superior* or *orbital*, directed upward and outward, of triangular form, concave, smooth, and forming the back part of the floor of the orbit; and the *external* or *zygomatic* surface, directed outward, backward, and downward, of an oblong form, smooth, lying in the spheno-maxillary fossa, and looking into the zygomatic fossa. The latter surface is separated from the orbital by a smooth, rounded border, which enters into the formation of the spheno-maxillary fissure.

The **Sphenoidal Process** of the palate bone is a thin, compressed plate, much smaller than the orbital, and directed upward and inward. It presents three surfaces and two borders. The *superior* surface, the smallest of the three, articulates with the under surface of the sphenoidal turbinated bone; it presents a groove, which contributes to the formation of the pterygo-palatine canal. The *internal* surface is concave, and forms part of the outer wall of the nasal fossa. The *external* surface is divided into an articular and a non-articular portion: the former is rough, for articulation with the inner surface of the internal pterygoid plate of the sphenoid; the latter is smooth, and forms part of the spheno-maxillary fossa. The *anterior* border forms the posterior boundary of the spheno-palatine foramen. The *posterior* border, serrated at the expense of the outer table, articulates with the inner surface of the internal pterygoid plate.

The orbital and sphenoidal processes are separated from one another by a deep notch, which is converted into a foramen, the *spheno-palatine*, by articulation with the sphenoidal turbinated bone. Sometimes the two processes are united above, and form between them a complete foramen, or the notch is crossed by one or more spiculæ of bone, so as to form two or more foramina. In the articulated skull this foramen opens into the back part of the outer wall of the superior meatus, and transmits the spheno-palatine vessels and the superior nasal and naso-palatine nerves.

Development.—From a single centre, which makes its appearance about the second month at the angle of junction of the two plates of the bone. From this point ossification spreads inward to the horizontal plate, downward into the tuberosity, and upward into the vertical plate. In the foetus the horizontal plate

is much longer than the vertical, and even after it is fully ossified the whole bone is at first remarkable for its shortness.

Articulations.—With six bones: the sphenoid, ethmoid, superior maxillary, inferior turbinated, vomer, and opposite palate.

Attachment of Muscles.—To four: the Tensor palati, Azygos uvulæ, Internal pterygoid, and Superior constrictor of the pharynx.

The Inferior Turbinated Bones.

The **Inferior Turbinated Bones** (*turbo*, a whirl) are situated one on each side of the outer wall of the nasal fossæ. Each consists of a layer of thin, spongy bone, curled upon itself like a scroll—hence its name “*turbinated*”—and extends horizontally along the outer wall of the nasal fossa, immediately below the orifice of

FIG. 60.—Inferior turbinated bone and Lachrymal bone *in situ*.

the antrum (Fig. 60). Each bone presents two surfaces, two borders, and two extremities.

The **internasal surface** (Fig. 61) is convex, perforated by numerous apertures, and traversed by longitudinal grooves and canals for the lodgement of arteries and

FIG. 61.—Right inferior turbinated bone. Internal surface.

FIG. 62.—Right inferior turbinated bone. External surface.

veins. In the recent state it is covered by the lining membrane of the nose. The **external surface** is concave (Fig. 62), and forms part of the inferior meatus. Its **upper border** is thin, irregular, and connected to various bones along the outer wall of the nose. It may be divided into three portions: of these, the anterior articulates with the inferior turbinated crest of the superior maxillary bone; the posterior with the inferior turbinated crest of the palate bone; the middle portion

of the superior border presents three well-marked processes, which vary much in their size and form. Of these, the anterior and smallest is situated at the junction of the anterior fourth with the posterior three-fourths of the bone: it is small and pointed, and is called the *lachrymal process*; it articulates by its apex with the anterior inferior angle of the lachrymal bone, and by its margins with the groove on the back of the nasal process of the superior maxillary, and thus assists in forming the canal for the nasal duct. At the junction of the two middle fourths of the bone, but encroaching on its posterior fourth, a broad, thin plate, the *ethmoidal process*, ascends to join the unciform process of the ethmoid; from the lower border of this process a thin lamina of bone curves downward and outward, hooking over the lower edge of the orifice of the antrum, which it narrows below: it is called the *maxillary process*, and fixes the bone firmly to the outer wall of the nasal fossa. The *inferior border* is free, thick, and cellular in structure, more especially in the middle of the bone. Bone *extremities* are more or less narrow and pointed, the posterior being the more tapering. If the bone is held so that its outer concave surface is directed backward (*i. e.*, toward the holder), and its superior border, from which the lachrymal and ethmoidal processes project, upward, the lachrymal process will be directed to the side to which the bone belongs.¹

Development.—By a single centre, which makes its appearance about the middle of foetal life.

Articulations.—With four bones: one of the cranium, the ethmoid, and three of the face, the superior maxillary, lachrymal, and palate.

No muscles are attached to this bone.

The Vomer.

The **Vomer** (*vomer*, a ploughshare) is a single bone, situated vertically at the back part of the nasal fossæ, forming part of the septum of the nose (Fig. 63).

FIG. 63.—Vomer *in situ*.

It is thin, somewhat like a ploughshare in form; but it varies in different indi-

¹ If the lachrymal process is broken off, as is often the case, the side to which the bone belongs may be known by recollecting that the maxillary process is nearer the back than the front of the bone.

viduals, being frequently bent to one or the other side; it presents for examination two surfaces and four borders. The *lateral surfaces* are smooth, marked by small furrows for the lodgement of blood-vessels, and by a groove on each side, some-

FIG. 64.—The vomer.

times a canal, the *naso-palatine*, which runs obliquely downward and forward to the intermaxillary suture; it transmits the naso-palatine nerve. The *superior border*, the thickest, presents a deep groove, bounded on each side by a horizontal projecting ala of bone; the groove receives the rostrum of the sphenoid, while the alæ are overlapped and retained by the *vaginal processes* which project from the under surface of the body of the sphenoid at the base of the pterygoid processes. At

the front of the groove a fissure is left for the transmission of blood-vessels to the substance of the bone. The *inferior border*, the longest, is broad and uneven in front, where it articulates with the two superior maxillary bones; thin and sharp behind, where it joins with the palate bones. The upper half of the *anterior border* usually consists of two laminæ of bone, between which is received the perpendicular plate of the ethmoid; the lower half, also separated into two lamellæ, receives between them the lower margin of the septal cartilage of the nose. The *posterior border* is free, concave, and separates the nasal fossæ behind. It is thick and bifid above, thin below.

The surfaces of the vomer are covered by mucous membrane, which is intimately connected with the periosteum, with the intervention of very little, if any, submucous connective tissue. Hence polypi are rarely found growing from this surface, though they frequently grow from the outer wall of the nasal fossæ, where the submucous tissue is abundant.

Development.—The vomer at an early period consists of two laminæ, separated by a very considerable interval, and enclosing between them a plate of cartilage, the *vomerine cartilage*, which is prolonged forward to form the remainder of the septum. Ossification commences in the membrane at the postero-inferior part of this cartilage by two centres, one on each side of the middle line, which extend to form the two laminæ. They begin to coalesce at the lower part, but their union is not complete until after puberty.

Articulations.—With six bones: two of the cranium, the sphenoid and ethmoid; and four of the face, the two superior maxillary and the two palate bones; and with the cartilage of the septum.

The vomer has no muscles attached to it.

The Inferior Maxillary Bone.

The **Inferior Maxillary Bone** (the *Mandible*), the largest and strongest bone of the face, serves for the reception of the lower teeth. It consists of a curved, horizontal portion, the *body*, and two perpendicular portions, the *rami*, which join the back part of the body nearly at right angles.

The **Horizontal Portion or Body** (Fig. 65) is convex in its general outline, and curved somewhat like a horseshoe. It presents for examination two surfaces and two borders. The *external surface* is convex from side to side, concave from above downward. In the median line is a vertical ridge, the *symphysis*, which extends from the upper to the lower border of the bone, and indicates the point of junction of the two pieces of which the bone is composed at an early period of life.

The lower part of the ridge terminates in a prominent triangular eminence, the *mental process*. This eminence is rounded below, and often presents a median depression separating two processes, the *mental tubercles*. It forms the chin, a feature peculiar to the human skull. On either side of the symphysis, just below the cavities for the incisor teeth, is a depression, the *incisive fossa*, for the attachment of the Levator menti (or Levator labii inferioris); more externally is attached a portion of the Orbicularis oris (*Accessorii Orbicularis inferioris*), and, still more externally, a foramen, the *mental foramen*, for the passage of the mental vessels and nerve. This foramen is placed just below the interval between the two bicuspid teeth. Running outward from the base of the mental process on each side is a ridge, the *external oblique line*. The ridge is at first nearly horizontal, but afterward inclines upward and backward, and is continuous with the anterior border of the ramus: it affords attachment to the Depressor

FIG. 65. — Inferior maxillary bone. Outer surface. Side view.

labii inferioris and Depressor anguli oris; below it the *Platysma myoides* is attached.

The *internal surface* (Fig. 66) is concave from side to side, convex from above downward. In the middle line is an indistinct linear depression, corresponding to the symphysis externally; on either side of this depression, just below its centre, are four prominent tubercles, placed in pairs, two above and two below; they are called the *genial tubercles*, and afford attachment, the upper pair to the *Genio-hyo-glossi*, the lower pair to the *Genio-hyoidei*, muscles. Sometimes the tubercles on each side are blended into one; at others they all unite into an irregular eminence; or, again, nothing but an irregularity may be seen on the surface of the bone at this part. On either side of the genial tubercles is an oval depression, the *sublingual fossa*, for lodging the sublingual gland; and beneath the fossa a rough depression on each side which gives attachment to the anterior belly of the *Digastric muscle*. At the back part of the sublingual fossa the *internal oblique line* (*mylo-hyoidean*) commences; it is at first faintly marked, but becomes more distinct as it passes upward and outward, and is especially prominent opposite the last two molar teeth; it affords attachment throughout its whole extent to the *Mylo-hyoid muscle*; the *Superior constrictor of the pharynx* with the *pterygo-maxillary ligament* being attached above its posterior extremity, near the alveolar margin. The portion of the bone above this ridge is smooth, and covered by the mucous membrane of the mouth; the portion below presents an oblong depression, the *submaxillary fossa*, wider behind than in front, for the lodgement of the submaxillary gland. The external oblique line and the internal or mylo-hyoidean line

divide the body of the bone into a superior or alveolar and an inferior or basilar portion.

The **superior** or **alveolar** border is wider, and its margins thicker, behind than in front. It is hollowed into numerous cavities, for the reception of the teeth; these cavities are sixteen in number, and vary in depth and size according to the teeth which they contain. To its outer side, the Buccinator muscle is attached as far forward as the first molar tooth. The **inferior** border is rounded, longer than the superior, and thicker in front than behind; it presents a shallow groove, just where the body joins the ramus, over which the facial artery turns.

FIG. 66. — Inferior maxillary bone. Inner surface. Side view.

The **Perpendicular Portions**, or **Rami**, are of a quadrilateral form. Each presents for examination two surfaces, four borders, and two processes. The *external surface* is flat, marked with ridges, and gives attachment throughout nearly the whole of its extent to the Masseter muscle. The *internal surface* presents about its centre the oblique aperture of the inferior dental canal, for the passage of the inferior dental vessels and nerve. The margin of this opening is irregular; it presents in front a prominent ridge, surmounted by a sharp spine, the *lingula*, which gives attachment to the internal lateral ligament of the lower jaw, and at its lower and back part a notch leading to a groove, the *mylo-hyoidean*, which runs obliquely downward to the back part of the submaxillary fossa, and lodges the mylo-hyoid vessels and nerve. Behind the groove is a rough surface, for the insertion of the Internal pterygoid muscle. The inferior dental canal runs obliquely downward and forward in the substance of the ramus, and then horizontally forward in the body; it is here placed under the alveoli, with which it communicates by small openings. On arriving at the incisor teeth, it turns back to communicate with the mental foramen, giving off two small canals, which run forward, to be lost in the cancellous tissue of the bone beneath the incisor teeth. This canal, in the posterior two-thirds of the bone, is situated nearer the internal surface of the jaw; and in the anterior third, nearer its external surface. Its walls are composed of compact tissue at either extremity, and of cancellous in the centre. It contains the inferior dental vessels and nerve, from which branches are distributed to the teeth through small apertures at the bases of the alveoli. The *lower border* of the ramus is thick, straight, and continuous with the body of the bone. At its junction with the posterior border is the *angle of the jaw*, which is either inverted or everted, and marked by rough, oblique ridges on each side, for

the attachment of the Masseter externally, and the Internal pterygoid internally; the stylo-maxillary ligament is attached to the angle between these muscles. The *anterior border* is thin above, thicker below, and continuous with the external oblique line. The *posterior border* is thick, smooth, rounded, and covered by the parotid gland. The *upper border* of the ramus is thin, and presents two processes, separated by a deep concavity, the *sigmoid notch*. Of these processes, the anterior is the *coronoid*, the posterior the *condyloid*.

The **Coronoid Process** is a thin, flattened, triangular eminence of bone, which varies in shape and size in different subjects, and serves chiefly for the attachment of the Temporal muscle. Its *external surface* is smooth, and affords attachment to the Temporal and Masseter muscles. Its *internal surface* gives attachment to the Temporal muscle and presents the commencement of a longitudinal ridge, which is continued to the posterior part of the alveolar process. On the outer side of this ridge is a deep groove, continued below on the outer side of the alveolar process; this ridge and part of the groove afford attachment, above, to the Temporal; below, to the Buccinator muscle.

The **Condyloid Process**, shorter but thicker than the coronoid, consists of two portions; the *condyle*, and the constricted portion which supports the condyle, the *neck*. The *condyle* is of an oblong form, its long axis being transverse, and set obliquely on the neck in such a manner that its outer end is a little more forward and a little higher than its inner. It is convex from before backward and from side to side, the articular surface extending farther on the posterior than on the anterior aspect. At its outer extremity is a small tubercle for the attachment of the external lateral ligament of the temporo-mandibular joint. The *neck* of the condyle is flattened from before backward, and strengthened by ridges which descend from the fore part and sides of the condyle. Its lateral margins are narrow, the external one giving attachment to part of the external lateral ligament. Its posterior surface is convex; its anterior is hollowed out on its inner side by a depression (the *pterygoid fossa*), for the attachment of the External pterygoid muscle.

The **Sigmoid Notch**, separating the two processes, is a deep semilunar depression, crossed by the masseteric vessels and nerve.

Development.—The lower jaw is developed principally from membrane, but partly from cartilage. The process of ossification commences early—earlier than in any other bone except the clavicle. The greater part of the bone is formed from a centre of ossification (dentary), which appears between the fifth and sixth week in the membrane on the outer surface of Meckel's cartilage. A second centre (*splénial*) appears in the membrane on the inner surface of the cartilage, and from this centre the inner wall of the sockets of the teeth is formed; this terminates above in the lingula. The anterior extremity of Meckel's cartilage becomes ossified, forming the body of the bone on each side of the symphysis. Two supplemental patches of cartilage appear at the condyle and at the angle, in each of which a centre of ossification for these parts appears; the coronoid process is also ossified from a separate centre. At birth the bone consists of two halves, united by a fibrous symphysis, in which ossification takes place during the first year.

Articulation.—With the glenoid fossæ of the two temporal bones.

Attachment of Muscles.—To fifteen pairs: to its external surface, commencing at the symphysis, and proceeding backward: Levator menti, Depressor labii inferioris, Depressor anguli oris, Platysma myoides, Buccinator, Masseter; a portion of the Orbicularis oris (*Accessorii orbicularis inferioris*) is also attached to this surface. To its internal surface, commencing at the same point: Genio-hyoglossus, Genio-hyoideus, Mylo-hyoideus, Digastric, Superior constrictor, Temporal, Internal pterygoid, External pterygoid.

CHANGES PRODUCED IN THE LOWER JAW BY AGE

The changes which the lower jaw undergoes after birth relate (1) to the alterations effected in the body of the bone by the first and second dentitions, the loss of the teeth in the aged, and

SIDE VIEW OF THE LOWER JAW AT DIFFERENT PERIODS OF LIFE.

FIG. 67.—At birth.

FIG. 68.—At seven years.

FIG. 69.—In the adult.

FIG. 70.—In old age.

the subsequent absorption of the alveoli; (2) to the size and situation of the dental canal; and (3) to the angle at which the ramus joins with the body.

At birth (Fig. 67) the bone consists of lateral halves, united by fibrous tissue. The body is a mere shell of bone, containing the sockets of the two incisor, the canine, and the two temporary molar teeth, imperfectly partitioned from one another. The dental canal is of large size, and runs near the lower border of the bone, the mental foramen opening beneath the socket of the first molar. The angle is obtuse (175°), and the condyloid portion nearly in the same horizontal line with the body; the neck of the condyle is short, and bent backward. The coronoid process is of comparatively large size, and situated at right angles with the rest of the bone.

After birth (Fig. 68) the two segments of the bone become joined at the symphysis, from below upward, in the first year; but a trace of separation may be visible in the beginning of the second year near the alveolar margin. The body becomes elongated in its whole length, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body becomes greater, owing to increased growth of the alveolar part, to afford room for the fangs of the teeth, and by thickening of the subdental portion, which enables the jaw to withstand the powerful action of the masticatory muscles; but the alveolar portion is the deeper of the two, and, consequently, the chief part of the body lies above the oblique line. The dental canal after the second dentition is situated just above the level of the mylo-hyoid ridge, and the mental foramen occupies the position usual to it in the adult. The angle becomes less obtuse, owing to the separation of the jaws by the teeth. (About the fourth year it is 140° .)

In the adult (Fig. 69) the alveolar and basilar portions of the body are usually of equal depth. The mental foramen opens midway between the upper and lower border of the bone, and the dental canal runs nearly parallel with the mylo-hyoid line. The ramus is almost vertical in direction, and joins the body nearly at right angles.

In old age (Fig. 70) the bone becomes greatly reduced in size; for with the loss of the teeth the alveolar process is absorbed, and the basilar part of the bone alone remains; consequently, the chief part of the bone is *below* the oblique line. The dental canal, with the mental foramen opening from it, is close to the alveolar border. The rami are oblique in direction, the angle obtuse, and the neck of the condyle more or less bent backward.

The Sutures.

The bones of the cranium and face are connected to each other by means of *Sutures*. That is, the articulating surfaces or edges of the bones are more or less roughened or uneven, and are closely adapted to each other, a small amount of intervening fibrous tissue, the *sutural ligament*, fastening them together. The *Cranial Sutures* may be divided into three sets: 1. Those at the vortex of the skull. 2. Those at the side of the skull. 3. Those at the base.

The sutures at the vertex of the skull are three: the *sagittal*, *coronal*, and *lambdoid*.

The **Sagittal Suture** (*interparietal*) is formed by the junction of the two parietal bones, and extends from the middle of the frontal bone backward to the superior angle of the occipital. In childhood, and occasionally in the adult, when the two halves of the frontal bone are not united, it is continued forward to the root of the nose. This suture is sometimes perforated, near its posterior extremity, by the parietal foramen; and in front, where it joins the coronal suture, a space is occasionally left which encloses a large Wormian bone.

The **Coronal Suture** (*fronto-parietal*) extends transversely across the vertex of the skull, and connects the frontal with the parietal bones. It commences at the extremity of the greater wing of the sphenoid on one side, and terminates at the same point on the opposite side. The dentations of the suture are more marked at the sides than at the summit, and are so constructed that the frontal rests on the parietal above, whilst laterally the frontal supports the parietal.

The **Lambdoid Suture** (*occipito-parietal*), so called from its resemblance to the Greek letter Λ , connects the occipital with the parietal bones. It commences on each side at the mastoid portion of the temporal bone, and inclines upward to the end of the sagittal suture. The dentations of this suture are very deep and distinct, and are often interrupted by several small Wormian bones.

The sutures at the side of the skull extend from the external angular process of the frontal bone to the lower end of the lambdoid suture behind. The anterior portion is formed between the lateral part of the frontal bone above and the malar and great wing of the sphenoid below, forming the *fronto-malar* and *fronto-*

sphenoidal sutures. These sutures can also be seen in the orbit, and form part of the so-called *transverse facial* suture. The posterior portion is formed between the parietal bone above and the great wing of the sphenoid, the squamous and mastoid portions of the temporal bone below, forming the *spheno-parietal*, *squamo-parietal*, and *masto-parietal* sutures.

The **Spheno-parietal** is very short; it is formed by the tip of the great wing of the sphenoid, which overlaps the anterior inferior angle of the parietal bone.

The **Squamo-parietal**, or **Squamous Suture**, is arched. It is formed by the squamous portion of the temporal bone overlapping the middle division of the lower border of the parietal.

The **Masto-parietal** is a short suture, deeply dentated, formed by the posterior inferior angle of the parietal and the superior border of the mastoid portion of the temporal.

The sutures at the base of the skull are the *basilar* in the centre, and on each side the *petro-occipital*, the *masto-occipital*, the *petro-sphenoidal*, and the *squamo-sphenoidal*.

The **Basilar Suture** is formed by the junction of the basilar surface of the occipital bone with the posterior surface of the body of the sphenoid. At an early period of life a thin plate of cartilage exists between these bones, but in the adult they become fused into one. Between the outer extremity of the basilar suture and the termination of the lambdoid an irregular suture exists, which is subdivided into two portions. The inner portion, formed by the union of the petrous part of the temporal with the occipital bone, is termed the **petro-occipital**. The outer portion, formed by the junction of the mastoid part of the temporal with the occipital, is called the **masto-occipital**. Between the bones forming the petro-occipital suture a thin plate of cartilage exists; in the masto-occipital is occasionally found the opening of the mastoid foramen. Between the outer extremity of the basilar suture and the spheno-parietal an irregular suture may be seen, formed by the union of the sphenoid with the temporal bone. The inner and smaller portion of this suture is termed the **petro-sphenoidal**; it is formed between the petrous portion of the temporal and the great wing of the sphenoid: the outer portion, of greater length and arched, is formed between the squamous portion of the temporal and the great wing of the sphenoid; it is called the **squamo-sphenoidal**.

The cranial bones are connected with those of the face, and the facial bones with each other, by numerous sutures, which, though distinctly marked, have received no special names. The only remaining suture deserving especial consideration is the **transverse**. This extends across the upper part of the face, and is formed by the junction of the frontal with the facial bones: it extends from the external angular process of one side to the same point on the opposite side, and connects the frontal with the malar, the sphenoid, the ethmoid, the lachrymal, the superior maxillary, and the nasal bones on each side.

The sutures remain separate for a considerable period after the complete formation of the skull. It is probable that they serve the purpose of permitting the growth of the bones at their margins, while their peculiar formation, together with the interposition of the sutural ligament between the bones forming them, prevents the dispersion of blows or jars received upon the skull. Humphry remarks, "that, as a general rule, the sutures are first obliterated at the parts in which the ossification of the skull was last completed—viz. in the neighborhood of the fontanelles; and the cranial bones seem in this respect to observe a similar law to that which regulates the union of the epiphyses to the shafts of the long bones." The same author remarks that the time of their disappearance is extremely variable: they are sometimes found well marked in skulls edentulous with age, while in others which have only just reached maturity they can hardly be traced. The obliteration of the sutures takes place sooner on the inner than on the outer surface of the skull. The sagittal and coronal sutures are as a rule the first to become ossified—the process starting near the posterior extremity of the former and the lower ends of the latter.

THE SKULL AS A WHOLE.

The Skull, formed by the union of the several cranial and facial bones already described, when considered as a whole is divisible into five regions: a superior region or vertex, an inferior region or base, two lateral regions, and an anterior region, the face.

The Vertex of the Skull.

The **Superior Region**, or **Vertex**, presents two surfaces, an external and an internal.

The **external surface** is bounded, in front, by the glabella and supraorbital ridges; behind, by the occipital protuberance and superior curved lines of the occipital bone; laterally, by an imaginary line extending from the outer end of the superior curved line, along the temporal ridge, to the external angular process of the frontal. This surface includes the greater part of the vertical portion of the frontal, the greater part of the parietal, and the superior third of the occipital bone; it is smooth, convex, of an elongated oval form, crossed transversely by the coronal suture, and from before backward by the sagittal, which terminates behind in the lambdoid. The point of junction of the coronal and sagittal sutures is named the *bregma*, and is represented by a line drawn vertically upward from the external auditory meatus, the head being in its normal position. The point of junction of the sagittal and lambdoid sutures is called the *lambda*, and is about $2\frac{3}{4}$ inches above the external occipital protuberance. From before backward may be seen the frontal eminences and remains of the suture connecting the two lateral halves of the frontal bone; on each side of the sagittal suture are the parietal foramen and parietal eminence, and still more posteriorly the convex surface of the occipital bone. In the neighborhood of the parietal foramen the skull is often flattened, and the name of *obelion* is sometimes given to that point of the sagittal suture which lies exactly opposite to the parietal foramen.

The **internal surface** is concave, presents depressions for the convolutions of the cerebrum, and numerous furrows for the lodgement of branches of the meningeal arteries. Along the middle line of this surface is a longitudinal groove, narrow in front, where it commences at the frontal crest, but broader behind, where it lodges the superior longitudinal sinus, and by its margin affords attachment to the falx cerebri. On either side of it are several depressions for the Pacchionian bodies, and at its back part the internal openings of the parietal foramina. This surface is crossed, in front, by the coronal suture; from before backward by the sagittal; behind, by the lambdoid.

The Base of the Skull.

The **Inferior Region**, or **Base of the Skull**, presents two surfaces—an internal or cerebral, and an external or basilar.

The **internal or cerebral surface** (Fig. 71) presents three fossæ, called the *anterior*, *middle*, and *posterior* fossæ of the cranium.

The **Anterior Fossa** is formed by the orbital plates of the frontal, the cribriform plate of the ethmoid, the anterior third of the superior surface of the body, and the upper surface of the lesser wings of the sphenoid. It is the most elevated of the three fossæ, convex externally where it corresponds to the roof of the orbit, concave in the median line in the situation of the cribriform plate of the ethmoid. It is traversed by three sutures, the *ethmo-frontal*, *ethmo-sphenoidal*, and *fronto-sphenoidal*, and lodges the frontal lobe of the cerebrum. It presents, in the median line, from before backward, the commencement of the groove for the superior longitudinal sinus and the frontal crest for the attachment of the falx cerebri; the *foramen cæcum*, an aperture formed between the frontal bone and the crista galli of the ethmoid, which, if pervious, transmits a small vein from the nose to the superior longitudinal sinus; behind the foramen cæcum, the *crista galli*, the posterior margin of which affords attachment to the falx cerebri; on either side of the crista galli, the cribriform plate, which supports the olfactory bulb. and

presents three rows of foramina for the transmission of its nervous filaments, and in front a slit-like opening for the nasal branch of the ophthalmic division

FIG. 71.—Base of the skull. Inner or cerebral surface.

of the fifth nerve. On the outer side of each olfactory groove are the internal openings of the *anterior* and *posterior ethmoidal foramina*; the former, situated about the middle of the outer margin of the olfactory groove, transmits the anterior ethmoidal vessels and the nasal nerve, which latter runs in a depression

along the surface of the ethmoid to the slit-like opening above mentioned; while the posterior ethmoidal foramen opens at the back part of this margin under cover of the projecting lamina of the sphenoid, and transmits the posterior ethmoidal vessels. Farther back in the middle line is the *ethmoidal spine*, bounded behind by a slight elevation, separating two shallow longitudinal grooves which support the olfactory lobes. Behind this is a transverse sharp ridge, running outward on either side to the anterior margin of the optic foramen, and separating the anterior from the middle fossa of the base of the skull. The anterior fossa presents, laterally, depressions for the convolutions of the brain and grooves for the lodgement of the anterior meningeal arteries.

The **Middle Fossa**, deeper than the preceding, is narrow in the middle line, but becomes wider at the side of the skull. It is bounded in front by the posterior margin of the lesser wing of the sphenoid, the anterior clinoid process, and the ridge forming the anterior margin of the optic groove; behind, by the superior border of the petrous portion of the temporal and the dorsum ephippii; externally by the squamous portion of the temporal, anterior inferior angle of the parietal bone, and greater wing of the sphenoid. It is traversed by four sutures, the squamo-parietal, sphenoparietal, squamo-sphenoidal, and petro-sphenoidal.

In the middle line, from before backward, is the *optic groove*, behind which lies the optic commissure; the groove terminates on each side in the optic foramen, for the passage of the optic nerve and ophthalmic artery; behind the optic groove is the *olivary process*, and laterally the *anterior clinoid processes*, to which are attached processes of the tentorium cerebelli. Farther back is the *sella turcica*, a deep depression which lodges the pituitary gland, bounded in front by a small eminence on either side, the *middle clinoid process*, and behind by a broad square plate of bone, the *dorsum ephippii*, surmounted at each superior angle by a tubercle, the *posterior clinoid process*; beneath the latter process is a notch, for the sixth nerve. On each side of the sella turcica is the *cavernous groove*: it is broad, shallow, and curved somewhat like the Italic letter *f*; it commences behind at the foramen lacerum medium, and terminates on the inner side of the anterior clinoid process, and presents along its outer margin a ridge of bone. This groove lodges the cavernous sinus, the internal carotid artery, and the nerves of the orbit. The sides of the middle fossa are of considerable depth; they present depressions for the convolutions of the brain and grooves for the branches of the middle meningeal artery; the latter commence on the outer side of the foramen spinosum, and consist of two large branches, an anterior and a posterior; the former passing upward and forward to the anterior inferior angle of the parietal bone, the latter passing upward and backward. The following foramina may also be seen from before backward: Most anteriorly is the *foramen lacerum anterius*, or *sphenoidal fissure*, formed above by the lesser wing of the sphenoid; below, by the greater wing; internally, by the body of the sphenoid; and sometimes completed externally by the orbital plate of the frontal bone. It transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch from the lachrymal artery to the dura mater, and the ophthalmic vein. Behind the inner extremity of the sphenoidal fissure is the *foramen rotundum*, for the passage of the second division of the fifth or superior maxillary nerve; still more posteriorly is seen a small orifice, the *foramen Vesalii*, an opening situated between the foramen rotundum and ovale, a little internal to both: it varies in size in different individuals, and is often absent; when present, it transmits a small vein. It opens below into the pterygoid fossa, just at the outer side of the scaphoid depression. Behind and external to the latter opening is the *foramen ovale*, which transmits the third division of the fifth or inferior maxillary nerve, the small meningeal artery, and the small petrosal nerve.¹ On the outer side of the foramen ovale is the *foramen spinosum*, for the passage of the middle meningeal artery; and

¹ See footnote, p. 74.

on the inner side of the foramen ovale, the *foramen lacerum medium*. The lower part of this aperture is filled with cartilage in the recent state. The Vidian nerve and a meningeal branch from the ascending pharyngeal artery pierce this cartilage. On the anterior surface of the petrous portion of the temporal bone is seen, from without inward, the eminence caused by the projection of the superior semicircular canal; in front of and a little outside this is a depression corresponding to the roof of the tympanum; the groove leading to the hiatus Fallopii, for the transmission of the petrosal branch of the Vidian nerve and the petrosal branch of the middle meningeal artery; beneath it, the smaller groove, for the passage of the lesser petrosal nerve; and, near the apex of the bone, the depression for the Gasserian ganglion; and the orifice of the carotid canal, for the passage of the internal carotid artery and carotid plexus of nerves.

The **Posterior Fossa**, deeply concave, is the largest of the three, and situated on a lower level than either of the preceding. It is formed by the posterior third of the superior surface of the body of the sphenoid, by the occipital, the petrous and mastoid portions of the temporal, and the posterior inferior angle of the parietal bone; it is crossed by four sutures, the petro-occipital, the masto-occipital, the masto-parietal, and the basilar; and lodges the cerebellum, pons Varolii, and medulla oblongata. It is separated from the middle fossa in the median line by the dorsum ephippii, and on each side by the superior border of the petrous portion of the temporal bone. This border serves for the attachment of the tentorium cerebelli, is grooved for the superior petrosal sinus, and at its inner extremity presents a notch, upon which rests the fifth nerve. The circumference of the fossa is bounded posteriorly by the grooves for the lateral sinuses. In the centre of this fossa is the *foramen magnum*, bounded on either side by a rough tubercle, which gives attachment to the odontoid or check ligaments; and a little above these are seen the internal openings of the *anterior condyloid foramina*, through which pass the hypoglossal nerve and a meningeal branch from the ascending pharyngeal artery. In front of the foramen magnum is a grooved surface, formed by the basilar process of the occipital bone and by the posterior third of the superior surface of the body of the sphenoid, which supports the medulla oblongata and pons Varolii, and articulates on each side with the petrous portion of the temporal bone, forming the petro-occipital suture, the anterior half of which is grooved for the inferior petrosal sinus, the posterior half being encroached upon by the *foramen lacerum posterius*, or *jugular foramen*. This foramen presents three compartments: through the anterior passes the inferior petrosal sinus; through the posterior, the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; and through the middle, the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. Above the jugular foramen is the *internal auditory meatus*, for the facial and auditory nerves and auditory artery; behind and external to this is the slit-like opening leading into the aquæductus vestibuli, which lodges the ductus endolymphaticus; while between the two latter, and near the superior border of the petrous portion, is a small, triangular depression, the remains of the floccular fossa, which lodges a process of the dura mater and occasionally transmits a small vein into the substance of the bone. Behind the foramen magnum are the *inferior occipital fossæ*, which lodge the hemispheres of the cerebellum, separated from one another by the *internal occipital crest*, which serves for the attachment of the falx cerebelli and lodges the occipital sinus. The posterior fossæ are surmounted, above, by the deep transverse grooves for the lodgment of the *lateral sinuses*. These channels, in their passage outward, groove the occipital bone, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and the jugular process of the occipital, and terminate at the back part of the jugular foramen. Where this sinus grooves the mastoid portion of the temporal bone the orifice of the *mastoid foramen* may be seen, and just previous to its termination it has opening into it the *posterior condyloid foramen*. Neither foramen is constant.

The **External Surface** of the Base of the Skull (Fig. 72) is extremely irregular.

FIG. 72.—Base of the skull. External surface.

It is bounded in front by the incisor teeth in the upper jaw; behind by the superior curved lines of the occipital bone; and laterally by the alveolar arch, the lower border of the malar bone, the zygoma, and an imaginary line extending

from the zygoma to the mastoid process and extremity of the superior curved line of the occiput. It is formed by the palate processes of the superior maxillary and palate bones, the vomer, the pterygoid processes, under surface of the great wing, spinous processes and part of the body of the sphenoid, the under surface of the squamous, mastoid, and petrous portions of the temporal, and the under surface of the occipital bone. The anterior part of the base of the skull is raised above the level of the rest of this surface (when the skull is turned over for the purpose of examination), surrounded by the alveolar process, which is thicker behind than in front, and excavated by sixteen depressions for lodging the teeth of the upper jaw, the cavities varying in depth and size according to the teeth they contain. Immediately behind the incisor teeth is the *anterior palatine fossa*. At the bottom of this fossa may usually be seen four apertures: two placed laterally, the *foramina of Stenson*, which open above, one in the floor of each nostril, and transmit the anterior branch of the posterior palatine vessels, and two in the median line in the intermaxillary suture, the *foramina of Scarpa*, one in front of the other, the anterior transmitting the left, and the posterior (the larger) the right, naso-palatine nerve. These two latter canals are sometimes wanting, or they may join to form a single one, or one of them may open into one of the lateral canals above referred to. The palatine vault is concave, uneven, perforated by numerous foramina, marked by depressions for the palatine glands, and crossed by a crucial suture, formed by the junction of the four bones of which it is composed. At the front part of this surface a delicate linear suture may frequently be seen, passing outward and forward from the anterior palatine fossa to the interval between the lateral incisor and canine teeth, and marking off the pre-maxillary portion of the bone. At each posterior angle of the hard palate is the *posterior palatine foramen*, for the transmission of the posterior palatine vessels and large descending palatine nerve; and running forward and inward from it a groove, for the same vessels and nerve. Behind the posterior palatine foramen is the *tuberosity of the palate bone*, perforated by one or more accessory posterior palatine canals, and marked by the commencement of a ridge, which runs transversely inward, and serves for the attachment of the tendinous expansion of the Tensor palati muscle. Projecting backward from the centre of the posterior border of the hard palate is the *posterior nasal spine*, for the attachment of the Azygos uvulæ muscle. Behind and above the hard palate is the posterior aperture of the nares, divided into two parts by the vomer, bounded above by the body of the sphenoid, below by the horizontal plate of the palate bone, and laterally by the internal pterygoid plate of the sphenoid. Each aperture measures about an inch in the vertical and about half an inch in the transverse direction. At the base of the vomer may be seen the expanded alæ of this bone, receiving between them, on each side, the rostrum of the sphenoid. Near the lateral margins of the vomer, at the root of the pterygoid processes, are the *pterygo-palatine canals*. The pterygoid process, which bounds the posterior nares on each side, presents near its base the *pterygoid* or *Vidian canal*, for the Vidian nerve and artery. Each process consists of two plates, which bifurcate at the extremity to receive the tuberosity of the palate bone, and are separated behind by the pterygoid fossa, which lodges the Internal pterygoid muscle. The internal plate is long and narrow, presenting on the outer side of its base the *scaphoid fossa*, for the origin of the Tensor palati muscle, and at its extremity the *hamular process*, around which the tendon of this muscle turns. The external pterygoid plate is broad, forms the inner boundary of the zygomatic fossa, and affords attachment by its outer surface to the External pterygoid muscle.

Behind the nasal fossæ in the middle line is the basilar surface of the occipital bone, presenting in its centre the *pharyngeal spine*, for the attachment of the Superior constrictor muscle of the pharynx, with depressions on each side for the insertion of the Rectus capitis anticus major and minor. At the base of the external pterygoid plate is the *foramen ovale*, for the transmission of the third division of the fifth nerve, the small meningeal artery, and sometimes the small petrosal nerve; behind this, the *foramen spinosum*, which transmits the middle

meningeal artery, and the prominent spinous process of the sphenoid, which gives attachment to the internal lateral ligament of the lower jaw and the Tensor palati muscle. External to the spinous process is the *glenoid fossa*, divided into two parts by the Glaserian fissure (page 66), the anterior portion concave, smooth, bounded in front by the eminentia articularis, and serving for the articulation of the condyle of the lower jaw; the posterior portion rough, bounded behind by the tympanic plate, and serving for the reception of part of the parotid gland. Emerging from between the laminae of the vaginal process of the tympanic plate is the *styloid process*, and at the base of this process is the *stylo-mastoid foramen*, for the exit of the facial nerve and entrance of the stylo-mastoid artery. External to the stylo-mastoid foramen is the *auricular fissure*, for the auricular branch of the pneumogastric, bounded behind by the mastoid process. Upon the inner side of the mastoid process is a deep groove, the *digastric fossa*; and a little more internally the *occipital groove*, for the occipital artery. At the base of the internal pterygoid plate is a large and somewhat triangular aperture, the *foramen lacerum medium*, bounded in front by the great wing of the sphenoid, behind by the apex of the petrous portion of the temporal bone, and internally by the body of the sphenoid and basilar process of the occipital bone: it presents in front the posterior orifice of the Vidian canal; behind, the aperture of the carotid canal. The basilar surface of this opening is filled in the recent state by fibro-cartilaginous substance; across its upper or cerebral aspect passes the internal carotid artery. External to this aperture the *petro-sphenoidal suture* is observed, at the outer termination of which is seen the orifice of the canal for the Eustachian tube and that for the Tensor tympani muscle. Behind this suture is seen the under surface of the petrous portion of the temporal bone, presenting, from within outward, the quadrilateral, rough surface, part of which affords attachment to the Levator palati and Tensor tympani muscles; external to this surface the orifices of the carotid canal and the aquæductus cochleæ, the former transmitting the internal carotid artery and the ascending branches of the superior cervical ganglion of the sympathetic, the latter serving for the passage of a small artery and vein to the cochlea. Behind the carotid canal is a large aperture, the *jugular foramen*, formed in front by the petrous portion of the temporal, and behind by the occipital; it is generally larger on the right than on the left side, and is divided into three compartments by processes of dura mater. The anterior is for the passage of the inferior petrosal sinus; the posterior, for the lateral sinus and some meningeal branches from the occipital and ascending pharyngeal arteries; the central one, for the glosso-pharyngeal, pneumogastric, and spinal accessory nerves. On the ridge of bone dividing the carotid canal from the jugular foramen is the small foramen for the transmission of Jacobson's nerve; and on the wall of the jugular foramen, near the root of the styloid process, is the small aperture for the transmission of Arnold's nerve. Behind the basilar surface of the occipital bone is the *foramen magnum*, bounded on each side by the condyles, rough internally for the attachment of the check or odontoid ligaments, and presenting externally a rough surface, the *jugular process*, which serves for the attachment of the Rectus capitis lateralis muscle and the lateral occipito-atlantal ligament. On either side of each condyle anteriorly is the *anterior condyloid fossa*, perforated by the anterior condyloid foramen, for the passage of the hypoglossal nerve and a meningeal artery. Behind each condyle is the *posterior condyloid fossa*, perforated on one or both sides by the posterior condyloid foramina, for the transmission of a vein to the lateral sinus. Behind the foramen magnum is the *external occipital crest*, terminating above at the *external occipital protuberance*, whilst on each side are seen the *superior* and *inferior curved lines*; these, as well as the surfaces of bone between them, are rough for the attachment of the muscles, which are enumerated on page 59.

The Lateral Region of the Skull.

The **Lateral Region** of the Skull is of a somewhat triangular form, the base of the triangle being formed by a line extending from the external angular process of the frontal bone along the temporal ridge backward to the outer extremity of the superior curved line of the occiput: and the sides by two lines, the one drawn downward and backward from the external angular process of the frontal bone to the angle of the lower jaw, the other from the angle of the jaw upward and

FIG. 73.—Side view of the skull. (Cryer.)

backward to the outer extremity of the superior curved line. This region is divisible into three portions—temporal fossa, mastoid portion, and zygomatic fossa.

The Temporal Fossa.

The **Temporal Fossa** is bounded above and behind by the temporal ridges, which extend from the external angular process of the frontal upward and backward across the frontal and parietal bones, curving downward behind to terminate in the posterior root of the zygomatic process (*supra-mastoid crest*). In front it is bounded by the frontal, malar, and great wing of the sphenoid; externally by the zygomatic arch formed conjointly by the malar and temporal bones; below, it is separated from the zygomatic fossa by the pterygoid ridge, seen on the outer surface of the great wing of the sphenoid. This fossa is formed by five bones, part of the frontal, great wing of the sphenoid, parietal, squamous portion of the temporal, and malar bones, and is traversed by six sutures, part of the transverse facial, speno-malar, coronal, speno-parietal, squamo-parietal, and squamo-sphenoidal. The point

where the coronal suture crosses the superior temporal ridge is sometimes named the *stephanion*; and the region where the four bones, the parietal, the frontal, the squamous, and the greater wing of the sphenoid, meet, at the anterior inferior angle of the parietal bone, is named the *pterion*. This point is about on a level with the external angular process of the frontal bone and about one and a half inches behind it. This fossa is deeply concave in front, convex behind, traversed by grooves which lodge branches of the deep temporal arteries, and filled by the Temporal muscles.

The Mastoid Portion.

The **Mastoid Portion** of the side of the skull is bounded in front by the tubercle of the zygoma; above, by a line which runs from the posterior root of the zygoma to the end of the mastoid-parietal suture; behind and below by the masto-occipital suture. It is formed by the mastoid and part of the squamous and petrous portions of the temporal bone; its surface is convex and rough for the attachment of muscles, and presents, from behind forward, the mastoid foramen, the mastoid process, the external auditory meatus surrounded by the tympanic plate, and, most anteriorly, the temporo-maxillary articulation.

The point where the posterior inferior angle of the parietal meets the occipital bone and mastoid portion of the temporal is named the *asterion*.

The Zygomatic Fossa.

The **Zygomatic Fossa** is an irregularly shaped cavity, situated below and on the inner side of the zygoma; bounded, in front, by the zygomatic surface of the superior maxillary bone and the ridge which descends from its malar process; behind, by the posterior border of the external pterygoid plate and the eminentia articularis; above, by the pterygoid ridge on the outer surface of the great wing

FIG. 74.—Zygomatic fossa.

of the sphenoid and the under part of the squamous portion of the temporal; below, by the alveolar border of the superior maxilla; internally, by the external pterygoid plate; and externally, by the zygomatic arch and ramus of the lower jaw (Fig. 74). It contains the lower part of the Temporal, the External and Internal pterygoid muscles, the internal maxillary artery and vein, and inferior max-

illary nerve and their branches. At its upper and inner part may be observed two fissures, the speno-maxillary and pterygo-maxillary.

The **Spheno-maxillary Fissure**, horizontal in direction, opens into the outer and back part of the orbit. It is formed above by the lower border of the orbital surface of the great wing of the sphenoid; below, by the external border of the orbital surface of the superior maxilla and a small part of the palate bone; externally, by a small part of the malar bone:¹ internally, it joins at right angles with the pterygo-maxillary fissure. This fissure opens a communication from the orbit into three fossæ—the temporal, zygomatic, and speno-maxillary; it transmits the superior maxillary nerve and its orbital branch, the infraorbital vessels, and ascending branches from the speno-palatine or Meckel's ganglion.

The **Pterygo-maxillary Fissure** is vertical, and descends at right angles from the inner extremity of the preceding; it is a V-shaped interval, formed by the divergence of the superior maxillary bone from the pterygoid process of the sphenoid. It serves to connect the speno-maxillary fossa with the zygomatic fossa, and transmits branches of the internal maxillary artery.

The Spheno-maxillary Fossa.

The **Spheno-maxillary Fossa** is a small, triangular space situated at the angle of junction of the speno-maxillary and pterygo-maxillary fissures, and placed beneath the apex of the orbit. It is formed above by the under surface of the body of the sphenoid and by the orbital process of the palate bone; in front, by the superior maxillary bone; behind, by the anterior surface of the base of the pterygoid process and lower part of the anterior surface of the great wing of the sphenoid; internally, by the vertical plate of the palate. This fossa has three fissures terminating in it—the *sphenoidal*, *spheno-maxillary*, and *pterygo-maxillary*; it communicates with the orbit by the speno-maxillary fissure; with the nasal fossæ by the speno-palatine foramen, and with the zygomatic fossa by the pterygo-maxillary fissure. It also communicates with the cavity of the cranium, and has opening into it five foramina. Of these, there are three on the posterior wall: the *foramen rotundum* above; below and internal to this, the *Vidian canal*; and still more inferiorly and internally, the *pterygo-palatine canal*. On the inner wall is the *spheno-palatine foramen*, by which the speno-maxillary communicates with the nasal fossa; and below is the superior orifice of the *posterior palatine canal*, besides occasionally the orifices of the *accessory posterior palatine canals*. The fossa contains the superior maxillary nerve and Meckel's ganglion, and the termination of the internal maxillary artery.

The Anterior Region of the Skull.

The **Anterior Region** of the Skull, which forms the face, is of an oval form, presents an irregular surface, and is excavated for the reception of two of the organs of sense, the eye and the nose. It is bounded above by the glabella and margins of the orbit; below, by the prominence of the chin; on each side by the malar bone and anterior margin of the ramus of the jaw. In the median line are seen from above downward the glabella, and diverging from it are the *superciliary ridges*, which indicate the situation of the frontal sinuses and support the eyebrows. Beneath the glabella is the fronto-nasal suture, the mid-point of which is termed the *nasion*, and below this is the arch of the nose, formed by the nasal bones, and the nasal processes of the superior maxillary. The nasal arch is convex from side to side, concave from above downward, presenting in the median line the inter-nasal suture formed between the nasal bones, laterally the naso-maxillary suture formed between the nasal bone and the nasal process of the superior maxillary bone. Below the nose is seen the opening of the anterior nares, which is heart-shaped, with the narrow end upward, and presents laterally the thin, sharp

¹ Occasionally the superior maxillary bone and the sphenoid articulate with each other at the anterior extremity of this fissure; the malar is then excluded from entering into its formation.

margins serving for the attachment of the lateral cartilages of the nose, and in the middle line below a prominent process, the *anterior nasal spine*, bounded by two deep notches. Below this is the *intermaxillary suture*, and on each side of it the *incisive fossa*. Beneath this fossa are the alveolar processes of the upper and lower jaws, containing the incisor teeth, and at the lower part of the median line the *symphysis of the chin*, the *mental process*, with its two *mental tubercles*, separated by a median groove, and the *incisive fossa* of the lower jaw.

On each side, proceeding from above downward, is the *supraorbital ridge*, terminating externally in the external angular process at its junction with the malar, and internally in the internal angular process; toward the inner third of this ridge is the *supraorbital notch or foramen*, for the passage of the supraorbital vessels and nerve. Beneath the supraorbital ridge is the opening of the orbit, bounded externally by the orbital ridge of the malar bone; below, by the orbital ridge formed by the malar and superior maxillary bones; internally, by the nasal process of the superior maxillary and the internal angular process of the frontal bone. On the outer side of the orbit is the quadrilateral anterior surface of the malar bone, perforated by one or two small malar foramina. Below the inferior margin of the orbit is the *infraorbital foramen*, the termination of the infraorbital canal, and beneath this the *canine fossa*, which gives attachment to the Levator anguli oris; still lower are the alveolar processes, containing the teeth of the upper and lower jaws. Beneath the alveolar arch of the lower jaw is the *mental foramen*, for the passage of the mental vessels and nerve, the *external oblique line*, and at the lower border of the bone, at the point of junction of the body with the ramus, a shallow groove for the passage of the facial artery.

The Orbits.

The Orbits (Fig. 75) are two quadrilateral pyramidal cavities, situated at the upper and anterior part of the face, their bases being directed forward and outward, and their apices backward and inward, so that the axes of the two, if continued backward, would meet over the body of the sphenoid bone. Each orbit is formed of *seven* bones, the frontal, sphenoid, ethmoid, superior maxillary, malar, lachrymal, and palate; but three of these, the frontal, ethmoid, and sphenoid, enter into the formation of *both* orbits, so that the two cavities are formed of *eleven* bones only. Each cavity presents for examination a roof, a floor, an inner and an outer wall, four angles, a circumference or base, and an apex. The roof is concave, directed downward and slightly forward, and formed in front by the orbital plate of the frontal; behind by the lesser wing of the sphenoid. This surface presents internally the depression for the cartilaginous pulley of the Superior oblique muscle; externally, the depression for the lachrymal gland; and posteriorly, the suture connecting the frontal and lesser wing of the sphenoid.

The *floor* is directed upward and outward, and is of less extent than the roof; it is formed chiefly by the orbital process of the superior maxillary; in front, to a small extent, by the orbital process of the malar, and behind, by the superior surface of the orbital process of the palate. This surface presents at its anterior and internal part, just external to the lachrymal groove, a depression for the attachment of the Inferior oblique muscle; externally, the suture between the malar and superior maxillary bones; near its middle, the infraorbital groove; and posteriorly, the suture between the maxillary and palate bones.

The *inner wall* is flattened, nearly vertical, and formed from before backward by the nasal process of the superior maxillary, the lachrymal, os planum of the ethmoid, and a small part of the body of the sphenoid. This surface presents the lachrymal groove and crest of the lachrymal bone, and the sutures connecting the lachrymal with the superior maxillary, the ethmoid with the lachrymal in front, and the ethmoid with the sphenoid behind.

The *outer wall* is directed forward and inward, and is formed in front by the orbital process of the malar bone; behind, by the orbital surface of the greater

wing of the sphenoid. On it are seen the orifices of one or two malar canals, and the suture connecting the sphenoid and malar bones.

Angles.—The *superior external angle* is formed by the junction of the upper and outer walls; it presents, from before backward, the suture connecting the frontal with the malar in front and with the great wing of the sphenoid behind; quite posteriorly is the foramen lacerum anterius, or sphenoidal fissure, which transmits the third, the fourth, the three branches of the ophthalmic division of the fifth, the sixth nerve, some filaments from the cavernous plexus of the sympathetic, the orbital branch of the middle meningeal artery, a recurrent branch

FIG. 75.—Antero-lateral region of the skull. (Cryer.)

from the lachrymal artery to the dura mater, and the ophthalmic vein. The *superior internal angle* is formed by the junction of the upper and inner wall, and presents the suture connecting the frontal bone with the lachrymal in front and with the ethmoid behind. The point of junction of the anterior border of the lachrymal with the frontal has been named the *dacryon*. This angle presents two foramina, the anterior and posterior ethmoidal, the former transmitting the anterior ethmoidal vessels and nasal nerve, the latter the posterior ethmoidal vessels. The *inferior external angle*, formed by the junction of the outer wall and floor, presents the speno-maxillary fissure, which transmits the superior maxillary nerve and its orbital branches, the infraorbital vessels, and the ascending branches from the speno-palatine or Meckel's ganglion. The *inferior internal angle* is formed by the union of the lachrymal and os planum of the ethmoid with the superior max-

illary and palate bones. The *circumference*, or base, of the orbit, quadrilateral in form, is bounded above by the supraorbital ridge; below, by the anterior border of the orbital plate of the malar and superior maxillary bones; externally, by the external angular process of the frontal and malar bones; internally, by the internal angular process of the frontal and the nasal process of the superior maxillary. The circumference is marked by three sutures, the fronto-maxillary internally, the fronto-malar externally, and the malo-maxillary below; it contributes to the formation of the lachrymal groove, and presents, above, the supraorbital notch (or foramen), for the passage of the supraorbital vessels and nerve. The *apex*, situated at the back of the orbit, corresponds to the optic foramen,¹ a short, circular canal which transmits the optic nerve and ophthalmic artery. It will thus be seen that there are *nine* openings communicating with each orbit—viz. the optic foramen, sphenoidal fissure, sphenomaxillary fissure, supraorbital foramen, infraorbital canal, anterior and posterior ethmoidal foramina, malar foramina, and canal for the nasal duct.

The Nasal Fossæ.

The **Nasal Fossæ** are two large, irregular cavities situated on either side of the middle line of the face, extending from the base of the cranium to the roof of the mouth, and separated from each other by a thin vertical septum. They communicate by two large apertures, the anterior nares, with the front of the face, and by the two posterior nares with the naso-pharynx behind. These fossæ are much

FIG. 76.—Roof, floor, and outer wall of left nasal fossa.

narrower above than below, and in the middle than at the anterior or posterior openings; their depth, which is considerable, is much greater in the middle than at either extremity. Each nasal fossa communicates with four sinuses, the frontal above, the sphenoidal behind, and the maxillary and ethmoidal on the outer wall.

¹ Quain, Testut, and others give the apex of the orbit as corresponding with the inner end of the sphenoidal fissure. It seems better, however, to adopt the statement in the text, since the muscles of the eyeball take origin around the optic foramen, and diverge from it to the globe of the eye.

Each fossa also communicates with four cavities: with the orbit by the lachrymal groove, with the mouth by the anterior palatine canal, with the cranium by the olfactory foramina, and with the spheno-maxillary fossa by the spheno-palatine foramen; and they occasionally communicate with each other by an aperture in the septum. The bones entering into their formation are fourteen in number: three of the cranium, the frontal, sphenoid, and ethmoid, and all the bones of the face, excepting the malar and lower jaw. Each cavity is bounded by a roof, a floor, an inner and an outer wall.

The **upper wall**, or **roof** (Fig. 76), is long, narrow, and horizontal in its centre, but slopes downward at its anterior and posterior extremities; it is formed in front by the nasal bones and nasal spine of the frontal, which are directed downward and forward; in the middle, by the cribriform plate of the ethmoid, which is horizontal; and behind, by the under surface of the body of the sphenoid and sphenoidal turbinated bones, the ala of the vomer and the sphenoidal process of the palate bone, which are directed downward and backward. This surface presents, from before backward, the internal aspect of the nasal bones; on their outer side, the suture formed between the nasal bone and the nasal process of the superior maxillary; on their inner side, the elevated crest which receives the nasal spine of the frontal and the perpendicular plate of the ethmoid, and articulates with its fellow of the opposite side; whilst the surface of the bones is perforated by a few small vascular apertures, and presents the longitudinal groove for the nasal nerve; farther back is the transverse suture, connecting the frontal with the nasal in front, and the ethmoid behind, the olfactory foramina and nasal slit on the under surface of the cribriform plate, and the suture between it and the sphenoid behind; quite posteriorly are seen the sphenoidal turbinated bones, the orifices of the sphenoidal sinuses, and the articulation of the alæ of the vomer with the under surface of the body of the sphenoid.

The **floor** is flattened from before backward, concave from side to side, and wider in the middle than at either extremity. It is formed in front by the palate process of the superior maxillary; behind, by the palate process of the palate bone. This surface presents, from before backward, the anterior nasal spine; behind this, the upper orifices of the anterior palatine canal; internally, the elevated crest which articulates with the vomer; and behind, the suture between the palate and superior maxillary bones, and the posterior nasal spine.

The **inner wall**, or **septum** (Fig. 77), is a thin vertical partition which separates the nasal fossæ from each other; it is occasionally perforated, so that the fossæ communicate, and it is frequently deflected considerably to one side.¹ It is formed, in front, by the crest of the nasal bones and nasal spine of the frontal; in the middle, by the perpendicular plate of the ethmoid; behind, by the vomer and rostrum of the sphenoid; below, by the crests of the superior maxillary and palate bones. It presents, in front, a large, triangular notch, which receives the septal cartilage of the nose; and behind, the grooved edge of the vomer. Its surface is marked by numerous vascular and nervous canals and the groove for the naso-palatine nerve, and is traversed by sutures connecting the bones of which it is formed.

The **outer wall** (Fig. 76) is formed, in front, by the nasal process of the superior maxillary and lachrymal bones; in the middle, by the ethmoid and inner surface of the superior maxillary and inferior turbinated bones; behind, by the vertical plate of the palate bone and the internal pterygoid plate of the sphenoid. This surface presents three irregular longitudinal passages, or *meatuses*, termed the superior, middle, and inferior meatuses of the nose. The *superior meatus*, the smallest of the three, is situated at the upper and back part of each nasal fossa, occupying the posterior third of the outer wall. It is situated between the superior and middle turbinated bones, and has opening into it two foramina, the *spheno-palatine* at the back of its outer wall, and the *posterior ethmoidal cells* at the front part of the outer wall. The sphenoidal sinus opens

¹ See footnote, p. 78.

into a recess, the *spheno-ethmoidal recess*, which is situated above and behind the superior turbinated bone. The *middle meatus* is situated between the middle and inferior turbinated bones, and extends from the anterior end of the inferior turbinated bone to the spheno-palatine foramen of the outer wall of the nasal fossa. It presents in front the orifice of the *infundibulum*, by which the middle meatus communicates with the anterior ethmoidal cells, and through these with the frontal sinuses. The middle ethmoidal cells also open into this meatus, while

FIG. 77.—Inner wall of nasal fossæ, or septum of nose.

at the centre of the outer wall is the *orifice of the antrum*, which varies somewhat as to its exact position in different skulls. The *inferior meatus*, the largest of the three, is the space between the inferior turbinated bone and the floor of the nasal fossa. It extends along the entire length of the outer wall of the nose, is broader in front than behind, and presents anteriorly the lower *orifice of the canal for the nasal duct*.

The **anterior nares** present a heart-shaped or pyriform opening whose long axis is vertical and narrow extremity upward. This opening in the recent state is much contracted by the cartilages of the nose. It is bounded above by the inferior border of the nasal bone; laterally by the thin, sharp margin which separates the facial from the nasal surface of the superior maxillary bone; and below by the same border, where it slopes inward to join its fellow of the opposite side at the anterior nasal spine.

The **posterior nares**, or *choanæ*, are the two posterior oval openings of the nasal fossæ, by which they communicate with the upper part of the pharynx. They are situated immediately in front of the basilar process, and are bounded above by the under surface of the body of the sphenoid and alæ of the vomer; below, by the posterior border of the horizontal plate of the palate bone; externally, by the inner surface of the internal pterygoid plate; and internally, in the middle line, they are separated from each other by the posterior border of the vomer.

Surface Form.—The various bony prominences or landmarks which are to be easily felt and recognized in the head and face, and which afford the means of mapping out the important structures comprised in this region, are as follows:

- | | |
|--|----------------------------|
| 1. Supraorbital arch. | 8. Parietal eminences. |
| 2. Internal angular process. | 9. Temporal ridge. |
| 3. External angular process. | 10. Frontal eminences. |
| 4. Zygomatic arch. | 11. Superciliary ridges. |
| 5. Mastoid process. | 12. Nasal bones. |
| 6. External occipital protuberance. | 13. Lower margin of orbit. |
| 7. Superior curved line of occipital bone. | 14. Lower jaw. |

1. The *supraorbital arches* are to be felt throughout their entire extent, covered by the eyebrows. They form the upper boundary of the circumference or base of the orbit, and separate the face from the forehead. They are strong and arched, and terminate internally on each side of the root of the nose in the *internal angular process*, which articulates with the lachrymal bone. Externally they terminate in the *external angular process*, which articulates with the malar bone. This arched ridge is sharper and more defined in its outer than in its inner half, and forms an overhanging process which protects and shields the lachrymal gland. It thus protects the eye in its most exposed situation and in the direction from which blows are most likely to descend. The supraorbital arch varies in prominence in different individuals. It is more marked in the male than in the female, and in some races of mankind than others. In the less civilized races, as the forehead recedes backward, the supraorbital arch becomes more prominent, and approaches more to the characters of the monkey tribe, in which the supraorbital arches are very largely developed, and acquire additional prominence from the oblique direction of the frontal bone. 2. The *internal angular process* is scarcely to be felt. Its position is indicated by the angle formed by the supraorbital arch with the nasal process of the superior maxillary bone and the lachrymal bone at the inner side of the orbit. Between the internal angular processes of the two sides is a broad surface which assists in forming the root of the nose, and immediately above this a broad, smooth, somewhat triangular surface, the *glabella*, situated between the superciliary ridges. 3. The *external angular process* is much more strongly marked than the internal, and is plainly to be felt. It is formed by the junction or confluence of the supraorbital and temporal ridges, and, articulating with the malar bone, it serves to a very considerable extent to support the bones of the face. In carnivorous animals the external angular process does not articulate with the malar, and therefore this lateral support to the bones of the face is not present. 4. The *zygomatic arch* is plainly to be felt throughout its entire length, being situated almost immediately under the skin. It is formed by the malar bone and the zygomatic process of the temporal bone. At its anterior extremity, where it is formed by the malar bone, it is broad and forms the prominence of the cheek; the posterior part is narrower, and terminates just in front and a little above the tragus of the external ear. The lower border is more plainly to be felt than the upper, in consequence of the dense temporal fascia being attached to the latter, which somewhat obscures its outline. Its shape differs very much in individuals and in different races of mankind. In the most degraded type of skull—as, for instance, in the skull of the negro of the Guinea Coast—the malar bones project forward and not outward, and the zygoma at its posterior extremity extends farther outward before it is twisted on itself to be prolonged forward. This makes the zygomatic arch stand out in bold relief, and affords greater space for the Temporal muscle. In skulls which have a more pyramidal shape, as in the Esquimaux or Greenlander, the malar bones do not project forward and downward under the eyes, as in the preceding form, but take a direction outward, forming with the zygoma a large, rounded sweep or segment of a circle. Thus it happens that if two lines are drawn from the zygomatic arches, touching the temporal ridges, they meet above the top of the head, instead of being parallel, or nearly so, as in the European skull, in which the zygomatic arches are not nearly so prominent. This gives to the face a more or less oval type. 5. Behind the ear is the *mastoid portion of the temporal bone*, plainly to be felt, and terminating below in a nipple-shaped process. Its anterior border can be traced immediately behind the concha, and its apex is on about a level with the lobule of the ear. It is rudimentary in infancy, but gradually develops in childhood, and is more marked in the negro than in the European. 6. The *external occipital protuberance* is always plainly to be felt just at the level where the skin of the neck joins that of the head. At this point the skull is thick for the purposes of safety, while radiating from it are numerous curved arches or buttresses of bone which give to this portion of the skull further security. 7. Running outward on either side from the external occipital protuberance is an arched ridge of bone, which can be more or less plainly perceived. This is the *superior curved line* of the occipital bone, and gives attachment to some of the muscles which keep the head erect on the spine; accordingly, we find it more developed in the negro tribes, in whom the jaws are much more massive, and therefore require stronger muscles to prevent their extra weight carrying the head forward. Below this line the surface of bone at the back of the head is obscured by the overlying muscles. Above it, the vault of the cranium is thinly covered with soft structures, so that the form of this part of the head is almost exactly that of the upper portion of the occipital, the parietal, and the frontal bones themselves; and in bald persons even the lines of junction of the bones, especially the junction of the occipital and parietal at the lambdoid suture, may be defined as a slight depression, caused by the thickening of the borders of the bones in this situation. 8. In the line of the greatest transverse diameter of the

head, on each side of the middle line, are generally to be found the *parietal eminences*, one on each side of the middle line, though sometimes these eminences are not situated at the point of the greatest transverse diameter, which is at some other prominent part of the parietal region. They denote the point where ossification of the parietal bone began. They are much more prominent and well-marked in early life, in consequence of the sharper curve of the bone at this period, so that it describes the segment of a smaller circle. Later in life, as the bone grows, the curve spreads out and forms the segment of a larger circle, so that the eminence becomes less distinguishable. In consequence of this sharp curve of the bone in early life, the whole of the vault of the skull has a squarer shape than it has in later life, and this appearance may persist in some rickety skulls. The eminence is more apparent in the negro's skull than in that of the European. This is due to greater flattening of the temporal fossa in the former skull to accommodate the larger Temporal muscle which exists in these races. The parietal eminence is particularly exposed to injury from blows or falls on the head, but fracture is to a certain extent prevented by the shape of the bone, which forms an arch, so that the force of the blow is diffused over the bone in every direction. 9. At the side of the head may be felt the *temporal ridge*. Commencing at the external angular process, it may be felt as a curved ridge, passing upward and then curving backward, on the frontal bone, separating the forehead from the temporal fossa. It may then be traced, passing backward in a curved direction, over the parietal bone, and, though less marked, still generally to be recognized. Finally, the ridge curves downward, and terminates in the posterior root of the zygoma, which separates the squamous from the subcutaneous mastoid portion of the temporal bone. Mr. Victor Horsley has recently shown, in an article on the "Topography of the Cerebral Cortex," that the second temporal ridge (see page 62) can be made out on the living body. 10. The *frontal eminences* vary a good deal in different individuals, being considerably more prominent in some than in others, and they are often not symmetrical on the two sides of the body, the one being much more pronounced than the other. This is often especially noticeable in the skull of the young child or infant, and becomes less marked as age advances. The prominence of the frontal eminences depends more upon the general shape of the whole bone than upon the size of the protuberances themselves. As the skull is more highly developed in consequence of increased intellectual capacity, so the frontal bone becomes more upright and the frontal eminences stand out in bolder relief. Thus they may be considered as affording, to a certain extent, an indication of the development of the hemispheres of the brain beneath, and of the mental powers of the individual. They are not so much exposed to injury as the parietal eminences. In falls forward the upper extremities are involuntarily thrown out, and break the force of the fall, and thus shield the frontal bone from injury. 11. Below the frontal eminences on the forehead are the *superciliary ridges*, which denote the position of the frontal sinuses, and vary according to the size of the sinuses in different individuals, being, as a rule, small in the female, absent in children, and sometimes unusually prominent in the male, when the frontal sinuses are largely developed. They commence on either side of the glabella, and at first present a rounded form, which gradually fades away at their outer ends. 12. The *nasal bones* form the prominence of the nose. They vary much in size and shape, and to them is due the varieties in the contour of this organ and much of the character of the face. Thus, in the Mongolian or Ethiopian they are flat, broad and thick at their base, giving to these tribes the flattened nose by which they are characterized, and differing very decidedly from the Caucasian, in whom the nose, owing to the shape of the nasal bones, is narrow, elevated at the bridge, and elongated downward. Below, the nasal bones are thin and connected with the cartilages of the nose, and the angle or arch formed by their union serves to throw out the bridge of the nose, and is much more marked in some individuals than others. 13. The *lower margin of the orbit*, formed by the superior maxillary bone and the malar bone, is plainly to be felt throughout its entire length. It is continuous internally with the nasal process of the superior maxillary bone, which forms the inner boundary of the orbit. At the point of junction of the lower margin of the orbit with the nasal process is to be felt a little tubercle of bone, which can be plainly perceived by running the finger along the bone in this situation. This tubercle serves as a guide to the position of the lachrymal sac, which is situated above and behind it. 14. The outline of the *lower jaw* is to be felt throughout its entire length. Just in front of the tragus of the external ear, and below the zygomatic arch, the condyle can be made out. When the mouth is opened this prominence of bone can be perceived advancing out of the glenoid fossa on to the eminentia articularis, and receding again when the mouth is closed. From the condyle the posterior border of the ramus can be felt extending down to the angle. A line drawn from the condyle to the angle would indicate the exact position of this border. From the angle to the symphysis of the chin the lower, rounded border of the body of the bone is plainly to be felt. At the point of junction of the two halves of the bone is a well-marked triangular eminence, the *mental process*, which forms the prominence of the chin.

Surgical Anatomy.—An arrest in the ossifying process may give rise to deficiencies or gaps; or to fissures, which are of importance in a medico-legal point of view, as they are liable to be mistaken for fractures. The fissures generally extend from the margin toward the centre of the bone, but gaps may be found in the middle as well as at the edges. In course of time they may become covered with a thin lamina of bone.

Occasionally a protrusion of the brain or its membranes may take place through one of these gaps in an imperfectly developed skull. When the protrusion consists of membranes only, and is filled with cerebro-spinal fluid, it is called a *meningocele*; when the protrusion consists of brain

as well as membranes, it is termed an *encephalocele*; and when the protruded brain is a prolongation from one of the ventricles, and is distended by a collection of fluid from an accumulation in the ventricle, it is termed an *hydrencephalocele*. This latter condition is frequently found at the root of the nose, where a protrusion of the anterior horn of the lateral ventricle takes place through a deficiency of the fronto-nasal suture. These malformations are usually found in the middle line, and most frequently at the back of the head, the protrusion taking place through the fissures which separate the four centres of ossification from which the tabular portion of the occipital bone is originally developed (see page 61). They most frequently occur through the upper part of the vertical fissure, which is the last to ossify, but not uncommonly through the lower part, when the foramen magnum may be incomplete. More rarely these protrusions have been met with in other situations than those two above mentioned, both through normal fissures, as the sagittal, lambdoid, and other sutures, and also through abnormal gaps and deficiencies at the sides, and even at the base of the skull.

Fractures of the skull may be divided into those of the vault and those of the base. Fractures of the vault are usually produced by direct violence. This portion of the skull varies in thickness and strength in different individuals, but, as a rule, is sufficiently strong to resist a very considerable amount of violence without being fractured. This is due to several causes: the rounded shape of the head and its construction of a number of secondary elastic arches, each made up of a single bone; the fact that it consists of a number of bones, united, at all events in early life, by a sutural ligament, which acts as a sort of buffer and interrupts the continuity of any violence applied to the skull; the presence of arches or ridges, both on the inside and outside of the skull, which materially strengthen it; and the mobility of the head upon the spine which further enables it to withstand violence. The elasticity of the bones of the head is especially marked in the skull of the child, and this fact, together with the wide separation of the individual bones from each other, and the interposition between them of other softer structures renders fracture of the bones of the head a very uncommon event in infants and quite young children; as age advances and the bones become joined, fracture is more common, though still less liable to occur than in the adult. Fractures of the vault may, and generally do, involve the whole thickness of the bone; but sometimes one table may be fractured without any corresponding injury to the other. Thus, the outer table of the skull may be splintered and driven into the diploë, or in the frontal or mastoid regions into the frontal or mastoid cells, without any injury to the internal table. And on the other hand, the internal table has been fractured, and portions of it depressed and driven inward, without any fracture of the outer table. As a rule, in fractures of the skull the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inward becomes broken up, and is more diffused by the time it reaches the inner table; the bone, being in the form of an arch, bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch—i. e. the outer table—and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force. Fractures of the vault may be simple fissures or starred and comminuted fractures, and these may be depressed or elevated. These latter cases of fracture with elevation of the fractured portion are uncommon, and can only be produced by direct wound. In comminuted fracture a portion of the skull is broken into several pieces, the lines of fracture radiating from a centre where the chief impact of the blow was felt; if depressed, a fissure circumscribes the radiating line, enclosing a portion of skull. If this area is circular, it is termed a "pond" fracture, and would in all probability have been caused by a round instrument, as a life-preserver or hammer; if elliptical in shape, it is termed a "gutter fracture," and would owe its shape to the instrument which had produced it, as a poker.

Fractures of the base are most frequently produced by the extension of a fissure from the vault, as in falls on the head, where the fissure starts from the part of the vault which first struck the ground. Sometimes, however, they are caused by direct violence, when foreign bodies have been forced through the thin roof of the orbit, through the cribriform plate of the ethmoid from being thrust up the nose, or through the roof of the pharynx. Other cases of fracture of the base occur from indirect violence, as in fracture of the occipital bone from impaction of the spinal column against its condyles in falls on the buttocks, knees, or feet, or in cases where the glenoid cavity has been fractured by the violent impact of the condyle of the lower jaw against it from blows on the chin.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighborhood of the parietal eminence, it runs downward through the parietal and squamous portion of the temporal bone and across the petrous portion of this bone, frequently traversing and implicating the internal auditory meatus, to the middle lacerated foramen. From this it may pass across the body of the sphenoid, through the pituitary fossa to the middle lacerated foramen of the other side, and may indeed travel round the whole cranium, so as to completely separate the anterior from the posterior part. The course of the fracture should be borne in mind, as it explains the symptoms to which fracture in this region may give rise; thus, if the fissure pass across the internal auditory meatus, injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; or the tubular prolongation of the arachnoid around these nerves in the meatus may be torn, and thus permit of the escape of the cerebro-spinal fluid should there be a communication between the internal ear

and the tympanum and the membrana tympani be ruptured, as is frequently the case; again, if the fissure passes across the pituitary fossa and the muco-periosteum covering the under surface of the body of the sphenoid is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal fossa, are generally the results of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and, travelling forward, appears as a subconjunctival ecchymosis. If the roof of the nasal fossa be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebro-spinal fluid from the nose where the dura mater and arachnoid have been torn. In fractures of the posterior fossa extravasation of blood may appear at the nape of the neck.

The bones of the skull are frequently the seat of nodes, and not uncommonly necrosis results from this cause, also from injury. Necrosis may involve the entire thickness of the skull, but is usually confined to the external table. Necrosis of the internal table alone is rarely met with. The bones of the skull are also frequently the seat of sarcomatous tumor.

The skull in rickets is peculiar: the forehead is high, square, and projecting, and the antero-posterior diameter of the skull is long in relation to the transverse diameter. The bones of the face are small and ill-developed, and this gives the appearance of a larger head than actually exists. The bones of the head are often thick, especially in the neighborhood of the sutures, and the anterior fontanelle is late in closing, sometimes remaining unclosed till the fourth year. The condition of *craniotabes* has by some been also believed to be the result of rickets, by others is believed to be due to inherited syphilis. In all probability it is due to both. In these cases the bone undergoes atrophic changes in patches, so that it becomes greatly thinned in places, generally where there is pressure, as from the pillow or nurse's arm. It is, therefore, usually met with in the parietal bone and vertical plate of the occipital bone.

In congenital syphilis deposits of porous bone are often found at the angles of the parietal bones and two halves of the frontal bone which bound the anterior fontanelle. These deposits are separated by the coronal and sagittal sutures, and give to the skull an appearance like a "hot cross bun." They are known as Parrot's nodes, and such a skull has received the name of *natiform*, from its fancied resemblance to the buttocks.

In connection with the bones of the face a common malformation is *cleft palate*, owing to the non-union of the palatal processes of the maxillary or pre-oral arch. This cleft may involve the whole or only a portion of the hard palate, and usually involves the soft palate also. The cleft is in the middle line, except it involves the alveolus in front, when it follows the suture between the main portion of the bone and the pre-maxillary bone. Sometimes the cleft runs on either side of the pre-maxillary bone, so that this bone is quite isolated from the maxillary bones and hangs from the end of the vomer. The malformation is usually associated with hare-lip, which, when single, is almost always on one side, corresponding to the position of the suture between the lateral incisor and canine tooth. Some few cases of median hare-lip have been described. In double hare-lip there is a cleft on each side of the middle line.

The bones of the face are sometimes fractured as the result of direct violence. The two most commonly broken are the nasal bone and the inferior maxilla, and of these the latter is by far the most frequently fractured of all the bones of the face. Fracture of the *nasal* bone is for the most part transverse, and takes place about half an inch from the free margin. The broken portion may be displaced backward or more generally to one side by the force which produced the lesion, as there are no muscles here which can cause displacement. The *malar* bone is probably never broken alone; that is to say, unconnected with a fracture of the other bones of the face. The *zygomatic arch* is occasionally fractured, and when this occurs from direct violence, as is usually the case, the fragments may be displaced inward. This lesion is often attended with great difficulty or even inability to open and shut the mouth, and this has been stated to be due to the depressed fragments perforating the temporal muscle, but would appear rather to be caused by the injury done to the bony origin of the Masseter muscle. Fractures of the *superior maxilla* may vary much in degree, from the chipping off of a portion of the alveolar arch, a frequent accident when the "old key" instrument was used for the extraction of teeth, to an extensive comminution of the whole bone from severe violence, as the kick of a horse. The most common situation for a fracture of the *inferior maxillary bone* is in the neighborhood of the canine tooth, as at this spot the jaw is weakened by the deep socket for the fang of this tooth; it is next most frequently fractured at the angle; then at the symphysis, and finally the neck of the condyle or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums. The displacement is mainly the result of the same violence as produced the injury, but may be further increased by the action of the muscles passing from the neighborhood of the symphysis to the hyoid bone.

The superior and inferior maxillary bones are both of them frequently the seat of necrosis, though the disease affects the lower much more frequently than the upper jaw, probably on account of the greater supply of blood to the latter. It may be the result of periostitis, from tooth irritation, injury, or the action of some specific poison, as syphilis, or from salivation by mercury; it not unfrequently occurs in children after attacks of the exanthematous fevers, and a special form occurs from the action of the fumes of phosphorus in persons engaged in the manufacture of matches.

Tumors attack the jaw-bones not infrequently, and these may be either innocent or malignant: in the upper jaw cysts may occur in the antrum, constituting the so-called dropsy of the antrum; or, again, cysts may form in either jaw in connection with the teeth: either cysts connected with the roots of fully-developed teeth, the "dental cyst;" or cysts connected with imperfectly developed teeth, the "dentigerous cyst." Solid innocent tumors include the fibroma, the chondroma, and the osteoma. Of malignant tumors there are two classes, the sarcomata and the epithelioma. The sarcoma are of various kinds, the spindle-celled and round-celled, of a very malignant character, and the myeloid sarcoma, principally affecting the alveolar margin of the bone. Of the epitheliomata we find the squamous variety spreading to the bone from the palate or gum, and the cylindrical epithelioma originating in the antrum or nasal fossæ.

Both superior and inferior maxillary bones occasionally require removal for tumors and in some other conditions. The upper jaw is removed by an incision from the inner canthus of the eye, along the side of the nose, round the ala, and down the middle line of the upper lip. A second incision is carried outward from the inner canthus of the eye along the lower margin of the orbit as far as the prominence of the malar bone. The flap thus formed is reflected outward and the surface of the bone exposed. The connections of the bone to the other bones of the face are then divided with a narrow saw. They are (1) the junction with the malar bone, passing into the sphenomaxillary fissure; (2) the nasal process; a small portion of its upper extremity, connected with the nasal bone in front, the lachrymal bone behind, and the frontal bone above, being left; (3) the connection with the bone on the opposite side and the palate in the roof of the mouth. The bone is now firmly grasped with lion-forceps, and by means of a rocking movement upward and downward the remaining attachments of the orbital plate with the ethmoid, and the back of the bone with the palate, broken through. The soft palate is first separated from the hard with a scalpel, and is not removed. Occasionally in removing the upper jaw it will be found that the orbital plate can be spared, and this should always be done if possible. A horizontal saw-cut is to be made just below the infraorbital foramen and the bone cut through with a chisel and mallet. Removal of one-half of the lower jaw is sometimes required. If possible, the section of the bone should be made to one side of the symphysis, so as to save the genial tubercles and the origin of the genio-hyo-glossus muscle, as otherwise the tongue tends to fall backward and may produce suffocation. Having extracted the central or preferably the lateral incisor tooth, a vertical incision is made down to the bone, commencing at the free margin of the lip, and carried to the lower border of the bone; it is then carried along its lower border to the angle and up the posterior margin of the ramus to a level with the lobule of the ear. The flap thus formed is raised by separating all the structures attached to the outer surface of the bone. The jaw is now sawn through at the point where the tooth has been extracted, and the knife passed along the inner side of the jaw, separating the structures attached to this surface. The jaw is then grasped by the surgeon and strongly depressed, so as to bring down the coronoid process and enable the operator to sever the tendon of the temporal muscle. The jaw can be now further depressed, care being taken not to evert it nor rotate it outward, which would endanger the internal maxillary artery, and the external pterygoid torn through or divided. The capsular ligament is now opened in front and the lateral ligaments divided, and the jaw removed with a few final touches of the knife.

The antrum of Highmore occasionally requires tapping for suppuration. This may be done through the socket of a tooth, preferably the first molar, the fangs of which are most intimately connected with the antrum, or through the facial aspect of the bone above the alveolar process. This latter method does not perhaps afford such efficient drainage, but there is less chance of food finding its way into the cavity. The operation may be performed by incising the mucous membrane above the second molar tooth, and driving a trocar or any sharp-pointed instrument into the cavity.

THE HYOID BONE.

The **Hyoid bone** is named from its resemblance to the Greek *upsilon*; it is also called the *lingual bone*, because it supports the tongue and gives attachment to its numerous muscles. It is a bony arch, shaped like a horseshoe, and consisting of five segments, a body, two greater cornua, and two lesser cornua. It is suspended from the tip of the styloid processes of the temporal bone by ligamentous bands, the *stylo-hyoid ligaments*.

The **Body** (*basi-hyal*) forms the central part of the bone, and is of a quadrilateral form; its *anterior surface* (Fig. 78), convex, directed forward and upward, is divided into two parts by a vertical ridge which descends along the median line, and is crossed at right angles by a horizontal ridge, so that this surface is divided into four spaces or depressions. At the point of meeting of these two lines is a prominent elevation, the *tubercle*. The portion above the horizontal ridge is directed upward, and is sometimes described as the superior border. The anterior surface gives attachment to the Genio-hyoid in the greater part of its extent; above, to the Genio-hyo-glossus; below, to the Mylo-hyoid, Stylo-hyoid, and

aponeurosis of the Digastric (suprahyoid aponeurosis); and between these to part of the Hyo-glossus. The *posterior surface* is smooth, concave, directed backward and downward, and separated from the epiglottis by the thyro-hyoid membrane and by a quantity of loose areolar tissue. The *superior border* is rounded, and gives attachment to the thyro-hyoid membrane, part of the Genio-hyo-glossi and Chondro-glossi muscles. The *inferior border* gives attachment, in front, to the Sterno-hyoid; behind, to the Omo-hyoid and to part of the Thyro-hyoid at its junction with the great cornu. It also gives attachment to the Levatore glandulæ thyroideæ when this muscle is present. The *lateral surfaces* after middle life are joined to the greater cornua. In early life they are connected to the cornua by cartilaginous surfaces, and held together by ligaments, and occasionally a synovial membrane is found between them.

FIG. 78.—Hyoid bone. Anterior surface. (Enlarged.)

The **Greater Cornua** (*thyro-hyal*) project backward from the lateral surfaces of the body; they are flattened from above downward, diminish in size from before backward, and terminate posteriorly in a tubercle for the attachment of the lateral thyro-hyoid ligament. The outer surface gives attachment to the Hyo-glossus, their upper border to the Middle constrictor of the pharynx, their lower border to part of the Thyro-hyoid muscle.

The **Lesser Cornua** (*cerato-hyals*) are two small, conical-shaped eminences attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments.¹ The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

The **Lesser Cornua** (*cerato-hyals*) are two small, conical-shaped eminences attached by their bases to the angles of junction between the body and greater cornua, and giving attachment by their apices to the stylo-hyoid ligaments.¹ The smaller cornua are connected to the body of the bone by a distinct diarthrodial joint, which usually persists throughout life, but occasionally becomes ankylosed.

Development.—By *five* centres: one for the body, and one for each cornu. Ossification commences in the body about the eighth month, and in the greater cornua toward the end of foetal life. Ossification of the lesser cornua commences some years after birth. Sometimes there are two centres for the body.

Attachment of Muscles.—Sterno-hyoid, Thyro-hyoid, Omo-hyoid, aponeurosis of the Digastric, Stylo-hyoid, Mylo-hyoid, Genio-hyoid, Genio-hyo-glossus, Chondro-glossus, Hyo-glossus, Middle constrictor of the pharynx, and occasionally a few fibres of the Inferior lingualis. It also gives attachment to the thyro-hyoidean membrane and the stylo-hyoid, thyro-hyoid, and hyo-epiglottic ligaments.

Surface Form.—The hyoid bone can be felt in the receding angle below the chin, and the finger can be carried along the whole length of the bone to the greater cornu, which is situated just below the angle of the jaw. This process of bone is best perceived by making pressure on one cornu, and so pushing the bone over to the opposite side, when the cornu of this side will be distinctly felt immediately beneath the skin. This process of bone is an important landmark in ligature of the lingual artery.

Surgical Anatomy.—The hyoid bone is occasionally fractured, generally from direct violence, as in the act of garrotting or throttling. The great cornu is the part of the bone most frequently broken, but sometimes the fracture takes place through the body of the bone. In consequence of the muscles of the tongue having important connections with this bone, there is great pain upon any attempt being made to move the tongue, as in speaking or swallowing.

¹ These ligaments in many animals are distinct bones, and in man are occasionally ossified to a certain extent.

THE THORAX.

The **Thorax**, or **Chest**, is an osseo-cartilaginous cage containing and protecting the principal organs of respiration and circulation. It is conical in shape, being narrow above and broad below, flattened from before backward, and longer behind than in front. It is somewhat reniform on transverse section.

Boundaries.—The *posterior* surface is formed by the twelve dorsal vertebræ and the posterior part of the ribs. It is concave from above downward, and presents on each side of the middle line a deep groove in consequence of the direction backward and outward which the ribs take from their vertebral extremities to their angles. The *anterior* surface is flattened or slightly convex, and inclined forward from above downward. It is formed by the sternum and costal cartilages. The *lateral* surfaces are convex; they are formed by the ribs, separated from each other by spaces, the *intercostal spaces*. These are eleven in number, and are occupied by the intercostal muscles.

The *upper opening* of the thorax is reniform in shape, being broader from side to side than from before backward. It is formed by the first dorsal vertebra behind, the upper margin of the sternum in front, and the first rib on each side. It slopes downward and forward, so that the anterior part of the ring is on a lower level than the posterior. The antero-posterior diameter is about two inches, and the transverse about four. The *lower opening* is formed by the twelfth dorsal vertebra behind, by the twelfth rib at the sides, and in front by the cartilages of the eleventh, tenth, ninth, eighth, and seventh ribs, which ascend on either side and form an angle, the *subcostal angle*, from the apex of which the ensiform cartilage projects. It is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm closes in the opening forming the floor of the thorax.

In the female the thorax differs as follows from the male: 1. Its general capacity is less. 2. The sternum is shorter. 3. The upper margin of the sternum is on a level with the lower part of the body of the third dorsal vertebra, whereas in the male it is on a level with the lower part of the body of the second dorsal vertebra. 4. The upper ribs are more movable, and so allow a greater enlargement of the upper part of the thorax than in the male.

The Sternum.

The **Sternum** (στέρνον, the chest) (Figs. 79, 80) is a flat, narrow bone, situated in the median line of the front of the chest, and consisting, in the adult, of three portions. It has been likened to an ancient sword; the upper piece, representing the handle, is termed the *manubrium*; the middle and largest piece, which represents the chief part of the blade, is termed the *gladiolus*; and the inferior piece, which is likened to the point of the sword, is termed the *ensiform* or *xiphoid appendix*. In its natural position its inclination is oblique from above downward and forward. It is slightly convex in front, concave behind, broad above, becoming narrowed at the point where the first and second pieces are connected, after which it again widens a little, and is pointed at its extremity. Its average length in the adult is about seven inches, being rather longer in the male than in the female.

The **First Piece** of the sternum, or **Manubrium** (*pre-sternum*), is of a somewhat triangular form, broad and thick above, narrow below at its junction with the middle piece. Its *anterior surface*, convex from side to side, concave from above downward, is smooth, and affords attachment on each side to the Pectoralis major and sternal origin of the Sterno-cleido-mastoid muscle. In well-marked bones the ridges limiting the attachment of these muscles are very distinct. Its *posterior surface*, concave and smooth, affords attachment on each side to the Sterno-hyoid and Sterno-thyroid muscles. The *superior border*, the thickest, presents at its centre the *pre-sternal notch*; and on each side an oval articular surface, directed

upward, backward, and outward, for articulation with the sternal end of the clavicle. The *inferior border* presents an oval, rough surface, covered in the recent state with a thin layer of cartilage, for articulation with the second portion of the bone. The *lateral borders* are marked above by a depression for the first costal cartilage, and below by a small facet, which with a similar facet on the upper angle of the middle portion of the bone, forms a notch for the reception of the costal cartilage of the second rib. These articular surfaces are separated by a narrow, curved edge, which slopes from above downward and inward.

The **Second Piece** of the sternum, or **Gladiolus** (*meso-sternum*), considerably longer, narrower, and thinner than the first piece, is broader below than above. Its *anterior surface* is nearly flat, directed upward and forward, and marked by three transverse lines which cross the bone opposite the third, fourth, and fifth articular depressions. These lines are produced by the union of the four separate pieces of which this part of the bone consists at an early period of life. At the junction of the third and fourth pieces is occasionally seen an orifice, the *sternal foramen*; it varies in size and form in different individuals, and pierces the bone from before backward. This surface affords attachment on each side to the sternal origin of the Pectoralis major. The *posterior surface*, slightly concave, is also marked by three transverse lines, but they are less distinct than those in front: this surface affords attachment below, on each side, to the Triangularis sterni muscle, and occasionally presents the posterior opening of the sternal foramen. The *superior border* presents an oval surface for articulation with the manubrium. The *inferior border* is narrow, and articulates with the ensiform appendix. Each *lateral border* presents, at each superior angle, a small facet, which, with a similar facet on the manubrium, forms a cavity for the cartilage of the second rib; the four succeeding angular depressions receive the cartilages of the third, fourth, fifth, and sixth ribs; whilst each inferior angle presents a small facet, which, with a corresponding one on the ensiform appendix, forms a notch for the cartilage of the seventh rib. These articular depressions are separated by a series of curved interarticular intervals, which diminish in length from above downward, and correspond to the intercostal spaces. Most of the cartilages belonging to the true ribs, as will be seen from the foregoing description, articulate with the sternum at the line of junction of two of its primitive component segments. This is well seen in many of the lower animals, where the separate parts of the bone remain ununited longer than in man. In this respect a striking analogy exists between the mode of connection of the ribs with the vertebral column and the connection of the costal cartilages with the sternum.

The **Third Piece** of the sternum, the **Ensiform** or **Xiphoid Appendix** (*meta-sternum*), is the smallest of the three; it is thin and elongated in form, cartilaginous in structure in youth, but more or less ossified at its upper part in the adult. Its *anterior surface* affords attachment to the chondro-xiphoid ligament; its *posterior surface*, to some of the fibres of the Diaphragm and Triangularis sterni muscles; its *lateral borders*, to the aponeurosis of the abdominal muscles. Above it articulates with the lower end of the gladiolus, and at each superior angle presents a facet for the lower half of the cartilage of the seventh rib; below, by its pointed extremity it gives attachment to the linea alba. This portion of the sternum is very various in appearance, being sometimes pointed, broad, and thin, sometimes bifid, or perforated by a round hole, occasionally curved or deflected considerably to one or the other side.

Structure.—The bone is composed of delicate cancellous structure, covered by a thin layer of compact tissue, which is thickest in the manubrium between the articular facets for the clavicles.

Development.—The cartilaginous sternum originally consists of two bars, situated one on either side of the mesial plane and connected with the rib cartilages of its own side. These two bars fuse with each other along the middle line, and the bone, including the ensiform appendix, is developed by *six* centres; one for the first piece or manubrium, four for the second piece or gladiolus, and one for the ensiform

FIG. 79.—Sternum and costal cartilages.

FIG. 80.—Posterior surface of sternum.

appendix. Up to the middle of foetal life the sternum is entirely cartilaginous, and when ossification takes place the ossific granules are deposited in the middle of the intervals between the articular depressions for the costal cartilages, in the following order (Fig. 81): In the first piece, between the fifth and sixth months; in the second and third, between the sixth and seventh months; in the fourth piece, at the ninth month; in the fifth, within the first year or between the first and second years after birth; and in the ensiform appendix, between the second and the seventeenth or eighteenth years, by a single centre which makes its appearance at the upper part and proceeds gradually downward. To these may be added the

FIG. 81.—Development of the sternum by six centres. Time of appearance.

FIG. 82.—Time of union of sternum.

occasional existence, as described by Breschet, of two small episternal centres, which make their appearance one on each side of the presternal notch. They are

FIG. 83.—Peculiarities in number of centres of sternum.

FIG. 84.—Peculiarities in mode of union of sternum.

probably vestiges of the episternal bone of the monotremata and lizards. It occasionally happens that some of the segments are formed from more than one centre, the number and position of which vary (Fig. 83). Thus, the first piece may have two, three, or even six centres. When two are present, they are generally situated one above the other, the upper one being the larger;¹ the second piece has seldom more than one; the third, fourth, and fifth pieces are often formed from two centres placed laterally, the irregular union of which will serve to explain the occasional occurrence of the sternal foramen (Fig. 84), or of the vertical fissure which occasionally intersects this part of the bone, and which is further explained by the manner in which the cartilaginous matrix, in which ossification takes place, is formed. Union of the various centres of the gladiolus commences about puberty, from below, and proceeds upward, so that by the age of twenty-

¹ Sir George Humphry states that this is "probably the more complete condition."

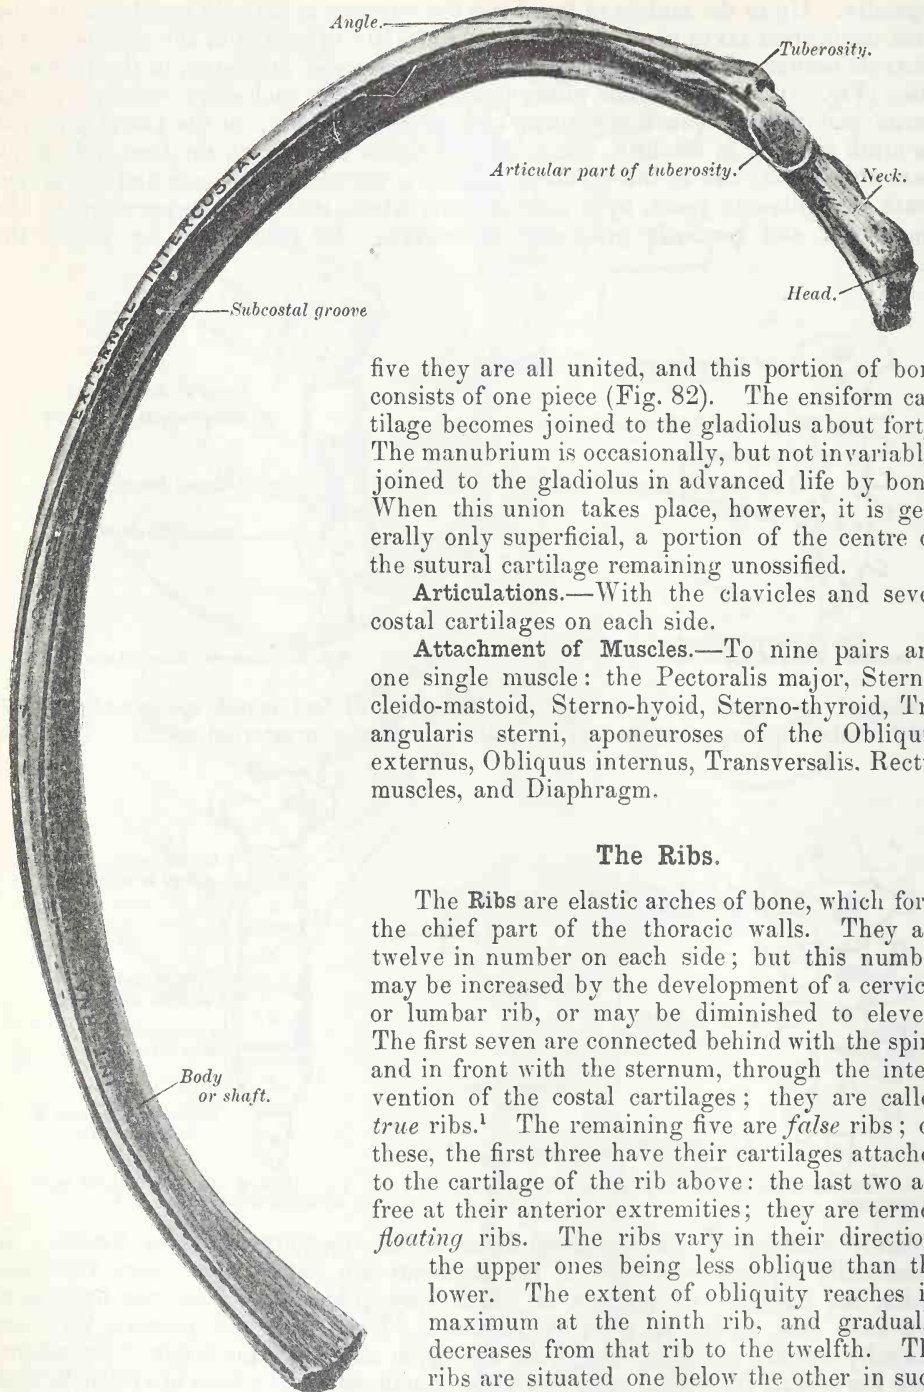

FIG. 85.—A central rib of left side.

five they are all united, and this portion of bone consists of one piece (Fig. 82). The ensiform cartilage becomes joined to the gladiolus about forty. The manubrium is occasionally, but not invariably, joined to the gladiolus in advanced life by bone. When this union takes place, however, it is generally only superficial, a portion of the centre of the sutural cartilage remaining unossified.

Articulations.—With the clavicles and seven costal cartilages on each side.

Attachment of Muscles.—To nine pairs and one single muscle: the Pectoralis major, Sternocleido-mastoid, Sterno-hyoid, Sterno-thyroid, Triangularis sterni, aponeuroses of the Obliquus externus, Obliquus internus, Transversalis. Rectus muscles, and Diaphragm.

The Ribs.

The **Ribs** are elastic arches of bone, which form the chief part of the thoracic walls. They are twelve in number on each side; but this number may be increased by the development of a cervical or lumbar rib, or may be diminished to eleven. The first seven are connected behind with the spine and in front with the sternum, through the intervention of the costal cartilages; they are called *true ribs*.¹ The remaining five are *false ribs*; of these, the first three have their cartilages attached to the cartilage of the rib above: the last two are free at their anterior extremities; they are termed *floating ribs*. The ribs vary in their direction, the upper ones being less oblique than the lower. The extent of obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs are situated one below the other in such a manner that spaces are left between them, which are called *intercostal spaces*. The

length of these spaces corresponds to the length of the ribs and their cartilages; their breadth is greater in front than behind, and between the upper than between the lower ribs. The ribs increase in length from the first to the seventh, when

¹Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right than on the left side.

they again diminish to the twelfth. In breadth they decrease from above downward; in the upper ten the greatest breadth is at the sternal extremity.

Common Characters of the Ribs (Fig. 85).—A rib from the middle of the series should be taken in order to study the common characters of the ribs.

Each rib presents two extremities, a posterior or vertebral, an anterior or sternal, and an intervening portion—the body or shaft.

The **posterior or vertebral extremity** presents for examination a head, neck, and tuberosity. The head (Fig. 86) is marked by a kidney-shaped articular surface, divided by a horizontal ridge into two facets for articulation with the costal cavity formed by the junction of the bodies of two contiguous dorsal vertebræ; the upper facet is small, the inferior one of larger size; the ridge separating them serves for the attachment of the interarticular ligament. The **neck** is that flattened portion of the rib which extends outward from the head; it is about an inch long, and is placed in front of the transverse process of the lower of the two vertebræ with which the head articulates. Its **anterior surface** is flat and smooth, its **posterior** rough for the attachment of the middle costo-transverse ligament, and perforated by numerous foramina, the direction of which is less constant than those found on the inner surface of the shaft. Of its two borders the **superior** presents a rough crest for the attachment of the anterior costo-transverse ligament; its **inferior border** is rounded. On the posterior surface of the neck, just where it

FIG. 86.—Vertebral extremity of a rib. External surface.

joins the shaft, and nearer the lower than the upper border, is an eminence—the **tuberosity**, or **tubercle**; it consists of an articular and a non-articular portion. The **articular portion**, the more internal and inferior of the two, presents a small, oval surface for articulation with the extremity of the transverse process of the lower of the two vertebræ to which the head is connected. The **non-articular portion** is a rough elevation, which affords attachment to the posterior costo-transverse ligament. The tubercle is much more prominent in the upper than in the lower ribs.

The **shaft** is thin and flat, so as to present two surfaces, an external and an internal, and two borders, a superior and an inferior. The **external surface** is convex, smooth and marked at its back part, a little in front of the tuberosity, by a prominent line, directed obliquely from above downward and outward; this gives attachment to a tendon of the *Ilio-costalis* muscle or of one of its accessory portions, and is called the **angle**. At this point the rib is bent in two directions. If the rib is laid upon its lower border, it will be seen that the portion of the shaft in front of the angle rests upon this border, while the portion of the shaft behind the angle is bent inward and at the same time tilted upward. The interval between the angle and the tuberosity increases gradually from the second to the tenth rib. The portion of bone between these two parts is rounded, rough, and irregular, and serves for the attachment of the *Longissimus dorsi* muscle. The portion of bone between the tubercle and sternal extremity is also slightly twisted upon its own axis, the external surface looking downward behind the angle, a little upward in front of it. This surface presents, toward its sternal extremity, an oblique line, the **anterior angle**. The **internal surface** is concave, smooth, directed a little upward behind the angle, a little downward in front of it. This surface

is marked by a ridge which commences at the lower extremity of the head; it is strongly marked as far as the inner side of the angle, and gradually becomes lost at the junction of the anterior with the middle third of the bone. The interval between it and the inferior border presents a groove, *subcostal*, for the intercostal vessels and nerve. At the back part of the bone this groove belongs to the inferior border, but just in front of the angle, where it is deepest and broadest, it corresponds to the internal surface. The superior edge of the groove is rounded; it serves for the attachment of the Internal intercostal muscle. The inferior edge corresponds to the lower margin of the rib and gives attachment to the External intercostal. Within the groove are seen the orifices of numerous small foramina which traverse the wall of the shaft obliquely from before backward. The *superior border*, thick and rounded, is marked by an external and an internal lip, more distinct behind than in front; they serve for the attachment of the External and Internal intercostal muscles. The *inferior border*, thin and sharp, has attached to it the External intercostal muscle. The *anterior or sternal extremity* is flattened, and presents a porous, oval, concave depression, into which the costal cartilage is received.

Peculiar Ribs.

The ribs which require especial consideration are five in number—viz. the first, second, tenth, eleventh and twelfth.

The **first rib** (Fig. 87) is one of the shortest and the most curved of all the ribs; it is broad and flat, its surfaces looking upward and downward, and its borders inward and outward. The *head* is of small size, rounded, and presents only a single articular facet for articulation with the body of the first dorsal vertebra. The *neck* is narrow and rounded. The *tuberosity*, thick and prominent, rests on the outer border. There is no angle, but in this situation the rib is slightly bent, with the convexity of the bend upward, so that the head of the bone is directed downward. The *upper surface* of the shaft is marked by two shallow depressions, separated by a small rough surface for the attachment of the Scalenus anticus muscle—the groove in front of it transmitting the subclavian vein, that behind it the subclavian artery. Between the groove for the subclavian artery and the tuberosity is a rough surface, for the attachment of the Scalenus medius muscle. The *under surface* is smooth, and destitute of the groove observed on the other ribs. The *outer border* is convex, thick, and rounded, and at its posterior part gives attachment to the first serration of the Serratus magnus; the *inner* is concave, thin, and sharp, and marked about its centre by the commencement of the rough surface for the Scalenus anticus. The *anterior extremity* is larger and thicker than any of the other ribs.

The **second rib** (Fig. 88) is much longer than the first, but bears a very considerable resemblance to it in the direction of its curvature. The non-articular portion of the tuberosity is occasionally only slightly marked. The *angle* is slight and situated close to the tuberosity, and the shaft is not twisted, so that both ends touch any plane surface upon which it may be laid; but there is a similar though slighter bend, with its convexity upward, to that found in the first rib. The shaft is not horizontal, like that of the first rib, its *outer surface*, which is convex, looking upward and a little outward. It presents, near the middle, a rough eminence for the attachment of the second and third digitations of the Serratus magnus; behind and above which is attached the Scalenus posticus. The *inner surface*, smooth and concave, is directed downward and a little inward; it presents a short groove toward its posterior part.

The **tenth rib** (Fig. 89) has only a single articular facet on its head.

The **eleventh and twelfth ribs** (Figs. 90 and 91) have each a single articular facet on the head, which is of rather large size; they have no neck or tuberosity, and are pointed at the extremity. The eleventh has a slight angle and a shallow groove on the lower border. The twelfth has neither, and is much shorter than the eleventh, and the head has a slight inclination downward. Sometimes the twelfth rib is even shorter than the first.

Structure.—The ribs consist of cancellous tissue enclosed in a thin, compact layer.

Development.—Each rib, with the exception of the last two, is developed by *three* centres : one for the shaft, one for the head, and one for the tubercle. The last two have only *two* centres, that for the tubercle being wanting. Ossification commences in the shaft of the ribs at a very early period, before its appearance in the vertebræ. The epiphysis of the head, which is of slightly angular shape, and that for the tubercle, of a lenticular form, make their appearance between the six-

FIGS. 87-91.—Peculiar ribs.

teenth and twentieth years, and are not united to the rest of the bone until about the twenty-fifth year.

Attachment of Muscles.—To nineteen : The Internal and External intercostals, Scalenus anticus, Scalenus medius, Scalenus posticus, Pectoralis minor, Serratus magnus, Obliquus externus, Quadratus lumborum, Diaphragm, Latissimus dorsi, Serratus posticus superior, Serratus posticus inferior, Ilio-costalis, Musculus accessorius ad ilio-costalem, Longissimus dorsi, Cervicalis ascendens, Levatores costarum, and Infracostales.

The Costal Cartilages.

The **Costal Cartilages** (Fig. 79, p. 126) are bars of white, hyaline cartilage, which serve to prolong the ribs forward to the front of the chest, and contribute very materially to the elasticity of its walls. The first seven are connected with the sternum, the next three with the lower border of the cartilage of the preceding rib. The cartilages of the last two ribs have pointed extremities, which terminate in free ends in the walls of the abdomen. Like the ribs, the costal cartilages vary in their length, breadth, and direction. They increase in length from the first to the seventh, then gradually diminish to the last. They diminish in breadth, as well as the intervals between them, from the first to the last. They are broad at their attachment to the ribs, and taper toward their sternal extremities, excepting the first two, which are of the same breadth throughout, and the sixth, seventh, and eighth, which are enlarged where their margins are in contact. In direction they also vary: the first descends a little, the second is horizontal, the third ascends slightly, while all the rest follow the course of the ribs for a short extent, and then ascend to the sternum or preceding cartilage. Each costal cartilage presents two surfaces, two borders, and two extremities. The *anterior surface* is convex, and looks forward and upward: that of the first gives attachment to the costo-clavicular ligament and the Subclavius muscle; that of the second, third, fourth, fifth, and sixth, at their sternal ends, to the Pectoralis major.¹ The others are covered by, and give partial attachment to, some of the great flat muscles of the abdomen. The *posterior surface* is concave, and directed backward and downward, the first giving attachment to the Sterno-thyroid, the third to the sixth inclusive to the Triangularis sterni, and the six or seven inferior ones to the Transversalis muscle and the Diaphragm. Of the two borders, the *superior* is concave, the *inferior* convex: they afford attachment to the internal Intercostal muscles, the upper border of the sixth giving attachment to the Pectoralis major muscle. The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages present small, smooth, oblong-shaped facets at the points where they articulate. Of the two extremities, the *outer* one is continuous with the osseous tissue of the rib to which it belongs. The *inner* extremity of the first is continuous with the sternum; the six succeeding ones have rounded extremities, which are received into shallow concavities on the lateral margins of the sternum. The inner extremities of the eighth, ninth, and tenth costal cartilages are pointed, and are connected with the cartilage above. Those of the eleventh and twelfth are free and pointed.

The costal cartilages are most elastic in youth, those of the false ribs being more so than the true. In old age they become of a deep yellow color, and are prone to calcify.

Attachment of Muscles.—To nine: the Subclavius, Sterno-thyroid, Pectoralis major, Internal oblique, Transversalis, Rectus, Diaphragm, Triangularis sterni, and Internal intercostals.

Surface Form.—The bones of the chest are to a very considerable extent covered by muscles, so that in the strongly-developed muscular subject they are for the most part concealed. In the emaciated subject, on the other hand, the ribs, especially in the lower and lateral region, stand out as prominent ridges with the sunken, intercostal spaces between them.

In the middle line, in front, the superficial surface of the sternum is to be felt throughout its entire length, at the bottom of a deep median furrow situated between the two great pectoral muscles and called the *sternal furrow*. These muscles overlap the anterior surface somewhat, so that the whole of the sternum in its entire width is not subcutaneous; and this overlapping is greater opposite the centre of the bone than above and below, so that the furrow is wider at its upper and lower parts, but narrower in the middle. The centre of the upper border of the sternum is visible, constituting the pre-sternal notch, but the lateral parts of this border are obscured by the tendinous origins of the Sterno-mastoid muscles, which present themselves as oblique tendinous cords, which narrow and deepen the notch. Lower down on the subcutaneous surface a well-defined transverse ridge, the angle of Ludovic, is always to be felt. This denotes the line of junction of the manubrium and body of the bone, and is a useful guide to the second costal cartilage, and thus to the identity of any given rib. The second rib being found through its

¹ The first and seventh also, occasionally, give origin to the same muscle.

costal cartilage, it is easy to count downward and find any other. From the middle of the sternum the furrow spreads out, and, exposing more of the surface of the body of the bone, terminates below in a sudden depression, the *infrasternal depression* or *pit of the stomach* (*scrobiculus cordis*), which corresponds to the ensiform cartilage. This depression lies between the cartilages of the seventh rib, and in it the ensiform cartilage may be felt. The sternum in its vertical diameter presents a general convexity forward, the most prominent point of which is at the joint between the manubrium and gladiolus.

On each side of the sternum the costal cartilages and ribs on the front of the chest are partially obscured by the great pectoral muscle; through which, however, they are to be felt as ridges, with yielding intervals between them, corresponding to the intercostal spaces. Of these spaces, the one between the second and third ribs is the widest, the next two somewhat narrower, and the remainder, with the exception of the last two, comparatively narrow.

The lower border of the Pectoralis major muscle corresponds to the fifth rib, and below this, on the front of the chest, the broad, flat outline of the ribs, as they begin to ascend, and the more rounded outline of the costal cartilages, are often visible. The lower boundary of the front of the thorax, the *abdomino-thoracic arch*, which is most plainly seen by arching the body backward, is formed by the ensiform cartilage and the cartilages of the seventh, eighth, ninth, and tenth ribs, and the extremities of the eleventh and twelfth ribs or their cartilages.

On each side of the chest, from the axilla downward, the flattened external surfaces of the ribs may be defined in the form of oblique ridges, separated by depressions corresponding to the intercostal spaces. They are, however, covered by muscles, which obscure their outline to a certain extent in the strongly developed. Nevertheless, the ribs, with the exception of the first, can generally be followed over the front and sides of the chest without difficulty. The first rib, being almost completely covered by the clavicle and scapula, can only be distinguished in a small portion of its extent. At the back the angles of the ribs form a slightly-marked oblique line on each side of and some distance from the vertebral spines. This line diverges somewhat as it descends, and external to it is a broad, convex surface caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Surgical Anatomy.—Malformations of the sternum present nothing of surgical importance beyond the fact that abscesses of the mediastinum may sometimes escape through the sternal foramen. Fractures of the sternum are by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages, which support it like so many springs. When broken it is frequently associated with fracture of the spine, and may be caused by forcibly bending the body either backward or forward until the chin becomes impacted against the top of the sternum. It may also be fractured by direct violence or by muscular action. The fracture usually occurs in the upper half of the body of the bone. Dislocation of the gladiolus from the manubrium also takes place, and is sometimes described as a fracture.

The bone, being subcutaneous, is frequently the seat of gummatous tumors, and not uncommonly is affected with caries. Occasionally the bone, and especially its ensiform appendix, becomes altered in shape and driven inward by the pressure, in workmen, of tools against their chest.

The ribs are frequently broken, though from their connections and shape they are able to withstand great force, yielding under the injury and recovering themselves like a spring. The middle of the series are the ones most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth, on account of their loose and floating condition, enjoy a like immunity. The fracture generally occurs from indirect violence, from forcible compression of the chest-wall, and the bone then gives way at its weakest part—i. e. just in front of the angle. But the ribs may also be broken by direct violence, when the bone gives way and is driven inward at the point struck, or they may be broken by muscular action. It seems probable, however, that in these latter cases the bone has undergone some atrophic changes. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity, and this is most likely to occur in fractures from direct violence.

Fracture of the costal cartilages may also take place, though it is a comparatively rare injury. The thorax is frequently found to be altered in shape in certain diseases.

The *rickety* thorax is caused chiefly by atmospheric pressure. The balance between the air on the inside of the chest and the outside during some stage of respiration is not equal, the preponderance being in favor of the air outside; and this, acting on the softened ribs, causes them to be forced in at the junction of the cartilages with the bones, which is the weakest part. In consequence of this the sternum projects forward, with a deep depression on either side caused by the sinking in of the softened ribs. The depression is less on the left side, on account of the ribs being supported by the heart. The condition is known as "pigeon-breast." The lower ribs, however, are not involved in this deformity, as they are prevented from falling in by the presence of the stomach, liver, and spleen. And when the liver and spleen are enlarged, as they sometimes are in rickets, the lower ribs may be pushed outward: this causes a transverse constriction just above the costal arch. The anterior extremities of the ribs are usually enlarged in rickets, giving rise to what has been termed the "rickety rosary." The *phthisical chest* is often long and narrow, flattened from before backward, and with great obliquity of the ribs and projection of the scapulæ. In *pulmonary emphysema* the chest is enlarged in all its diameters, and presents on section an almost circular outline. It has received the name of the

"barrel-shaped chest." In severe cases of *lateral curvature of the spine* the thorax becomes much distorted. In consequence of the rotation of the bodies of the vertebræ which takes place in this disease the ribs opposite the convexity of the dorsal curve become extremely convex behind, being thrown out and bulging, and at the same time flattened in front, so that the two ends of the same rib are almost parallel. Coincident with this, the ribs on the opposite side, on the concavity of the curve, are sunk and depressed behind and bulging and convex in front. In addition to this the ribs become occasionally welded together by bony material.

The ribs are frequently the seat of necrosis leading to abscesses and sinuses, which may burrow to a considerable extent over the wall of the chest. The only special anatomical point in connection with these is that care must be taken in dealing with them that the intercostal space is not punctured and the pleural cavity opened or the intercostal vessels wounded, as the necrosed portion of bone is generally situated on the internal surface of the rib.

In cases of empyema the chest requires opening to evacuate the pus. There is considerable difference of opinion as to the best position to do this. Probably the best place in most cases will be found to be between the fifth and sixth ribs, in or a little in front of the mid-axillary line. This is the last part of the cavity to be closed by the expansion of the lung; it is not thickly covered by soft parts; the space between the two ribs is sufficiently great to allow of the introduction of a fair-sized drainage-tube, and the opening is in a dependent position, when the patient is confined to bed, as he usually inclines toward the affected side, so as to allow the sound lung the freest possible play, and so permits of efficient drainage.

THE EXTREMITIES.

The extremities, or limbs, are those long, jointed appendages of the body which are connected to the trunk by one end and free in the rest of their extent. They are *four* in number: an *upper* or *thoracic pair*, connected with the thorax through the intervention of the shoulder, and subservient mainly to prehension; and a *lower pair*, connected with the pelvis, intended for support and locomotion. Both pairs of limbs are constructed after one common type, so that they present numerous analogies, while at the same time certain differences are observed between the upper and lower pair, dependent on the peculiar offices they have to perform.

The bones by which the upper and lower limbs are attached to the trunk are named respectively the *shoulder* and *pelvic girdles*, and they are constructed on the same general type, though presenting certain modifications relating to the different uses to which the upper and lower limbs are respectively applied. The *shoulder girdle* is formed by the scapula and clavicle, and is imperfect in front and behind. In front, however, the girdle is completed by the upper end of the sternum, with which the inner extremities of the clavicle articulate. Behind, the girdle is widely imperfect and the scapula is connected to the trunk by muscles only. The *pelvic girdle* is formed by the innominate bones, and is completed in front through the symphysis pubis, at which the two innominate bones articulate with each other. It is imperfect behind, but the intervening gap is filled in by the upper part of the sacrum. The pelvic girdle, therefore, presents, with the sacrum, a complete ring, comparatively fixed, and presenting an arched form which confers upon it a solidity manifestly intended for the support of the trunk, and in marked contrast to the lightness and mobility of the shoulder girdle.

With regard to the morphology of these girdles, the blade of the scapula is generally believed to correspond to the ilium; but with regard to the clavicles there is some difference of opinion: formerly it was believed that they corresponded to the ossa pubis, meeting at the symphysis, but it is now generally taught that the clavicle has no homologue in the pelvic girdle, and that the os pubis and ischium are represented by the small coracoid process in man and most mammals.

THE UPPER EXTREMITY.

The bones of the upper extremity consist of those of the shoulder girdle, of the arm, the forearm, and the hand.

THE SHOULDER GIRDLE.

The shoulder girdle consists of two bones, the clavicle and the scapula.

The Clavicle.

The **Clavicle** (*clavis*, a key), or collar-bone, forms the anterior portion of the shoulder girdle. It is a long bone, curved somewhat like the italic letter *f*, and placed nearly horizontally at the upper and anterior part of the thorax, immediately above the first rib. It articulates by its inner extremity with the upper border of the sternum, and by its outer extremity with the acromion process of the scapula, serving to sustain the upper extremity in the various positions which it assumes, whilst at the same time it allows of great latitude of motion in the arm.¹ It presents a double curvature when looked at in front, the convexity being forward at the sternal end and the concavity at the scapular end. Its outer third is flattened from above downward, and extends, in the natural position of the bone, from a point opposite the coracoid process to the acromion. Its inner two-thirds are of a prismatic form, and extend from the sternum to a point opposite the coracoid process of the scapula.

External or Flattened Portion.—The *outer third* is flattened from above downward, so as to present two surfaces, an upper and a lower; and two borders, an anterior and a posterior. The *upper surface* is flattened, rough, marked by impressions for the attachment of the Deltoid in front and the Trapezius behind; between these two impressions, externally, a small portion of the bone is subcutaneous. The *under surface* is flattened. At its posterior border, a little external to the point where the prismatic joins with the flattened portion, is a rough eminence, the *conoid tubercle*; this, in the natural position of the bone, surmounts the coracoid process of the scapula and gives attachment to the conoid ligament. From this tubercle an oblique line, occasionally a depression, passes forward and outward to near the outer end of the anterior border; it is called the *oblique line* or *trapezoid ridge*, and affords attachment to the trapezoid ligament. The *anterior border* is concave, thin, and rough, and gives attachment to the Deltoid; it occasionally presents, at its inner end, at the commencement of the deltoid impression, a tubercle, the *deltoid tubercle*, which is sometimes to be felt in the living subject. The *posterior border* is convex, rough, broader than the anterior, and gives attachment to the Trapezius.

Internal or Prismatic Portion.—The prismatic portion forms the *inner two-thirds* of the bone. It is curved so as to be convex in front, concave behind, and is marked by three borders, separating three surfaces. The *anterior border* is continuous with the anterior margin of the flat portion. At its commencement it is smooth, and corresponds to the interval between the attachment of the Pectoralis major and Deltoid muscles; at the inner half of the clavicle it forms the lower boundary of an elliptical space for the attachment of the clavicular portion of the Pectoralis major, and approaches the posterior border of the bone. The *superior border* is continuous with the posterior margin of the flat portion, and separates the anterior from the posterior surface. At its commencement it is smooth and rounded, becomes rough toward the inner third for the attachment of the Sternomastoid muscle, and terminates at the upper angle of the sternal extremity. The *posterior* or *subclavian border* separates the posterior from the inferior surface, and extends from the conoid tubercle to the rhomboid impression. It forms the posterior boundary of the groove for the Subclavius muscle, and gives attachment to a layer of cervical fascia covering the Omo-hyoid muscle. The *anterior surface* is included between the superior and anterior borders. It is directed forward and a little upward at the sternal end, outward and still more upward at the acromial extremity, where it becomes continuous with the upper surface of the flat portion. Externally, it is smooth, convex, nearly subcutaneous, being covered only by the

¹ The clavicle acts especially as a fulcrum to enable the muscles to give lateral motion to the arm. It is accordingly absent in those animals whose fore limbs are used only for progression, but is present for the most part in those animals whose anterior extremities are clawed and used for prehension, though in some of them—as, for instance, in a large number of the carnivora—it is merely a rudimentary bone suspended among the muscles, and not articulating either with the scapula or sternum.

Platysma; but, corresponding to the inner half of the bone, it is divided by a more or less prominent line into two parts: a lower portion, elliptical in form, rough, and slightly convex, for the attachment of the Pectoralis major; and an upper part, which is rough, for the attachment of the Sterno-cleido-mastoid. Between the two muscular impressions is a small subcutaneous interval. The *posterior or cervical surface* is smooth, flat, and looks backward toward the root of the neck. It is limited, above, by the superior border; below, by the subclavian border; internally, by the margin of the sternal extremity; externally, it is continuous with the posterior border of the flat portion. It is concave from within outward, and is in relation, by its lower part, with the suprascapular vessels. This surface, at about the junction of the inner and outer curves, is also in close relation with the brachial plexus and subclavian vessels. It gives attachment, near the sternal extremity, to part of the Sterno-hyoid muscle; and presents, at or near the middle, a foramen, directed obliquely outward, which transmits the chief nutrient artery of the bone. Sometimes there are two foramina on the posterior surface, or one on the posterior, the other on the inferior surface. The *inferior or subclavian*

FIG. 92.—Left clavicle. Superior surface.

surface is bounded, in front, by the anterior border; behind, by the subclavian border. It is narrow internally, but gradually increases in width externally, and

FIG. 93.—Left clavicle. Inferior surface.

is continuous with the under surface of the flat portion. Commencing at the sternal extremity may be seen a small facet for articulation with the cartilage of the first rib. This is continuous with the articular surface at the sternal end of the bone. External to this is a broad, rough surface, the *rhomboid impression*, rather more than an inch in length, for the attachment of the costo-clavicular (rhomboid) ligament. The remaining part of this surface is occupied by a longitudinal groove, the *subclavian groove*, broad and smooth externally, narrow and more uneven internally; it gives attachment to the Subclavius muscle, and by its margins to the costo-coracoid membrane, which splits to enclose a muscle. Not infrequently this groove is subdivided into two parts by a longitudinal line, which gives attachment to the intermuscular septum of the Subclavius muscle.

The *internal or sternal extremity* of the clavicle is triangular in form, directed

inward and a little downward and forward; and presents an articular facet, concave from before backward, convex from above downward, which articulates with the sternum through the intervention of an interarticular fibro-cartilage; the circumference of the articular surface is rough, for the attachment of numerous ligaments. The posterior border of this surface is prolonged backward, so as to increase the size of the articular facet; the upper border gives attachment to the interarticular fibro-cartilage, and the lower border is continuous with the costal facet on the inner end of the inferior or subclavian surface, which articulates with the cartilage of the first rib.

The **outer or acromial extremity**, directed outward and forward, presents a small, flattened, oval facet, which looks obliquely downward, for articulation with the acromion process of the scapula. The circumference of the articular facet is rough, especially above, for the attachment of the acromio-clavicular ligaments.

Peculiarities of the Bone in the Sexes and in Individuals.—In the female the clavicle is generally shorter, thinner, less curved, and smoother than in the male. In those persons who perform considerable manual labor, which brings into constant action the muscles connected with this bone, it becomes thicker and more curved, its ridges for muscular attachment become prominently marked. The right clavicle is generally longer, thicker, and rougher than the left.

Structure.—The shaft, as well as the extremities, consists of cancellous tissue, invested in a compact layer much thicker in the middle than at either end. The clavicle is highly elastic, by reason of its curves. From the experiments of Mr. Ward it has been shown that it possesses sufficient longitudinal elastic force to project its own weight nearly two feet on a level surface when a smart blow is struck on it; and sufficient transverse elastic force, opposite the centre of its anterior convexity, to throw its own weight about a foot. This extent of elastic power must serve to moderate very considerably the effect of concussions received upon the point of the shoulder.

Development.—By *two* centres: one for the shaft and one for the sternal extremity. The centre for the shaft appears very early, before any other bone—according to Béclard, as early as the thirtieth day. The centre for the sternal end makes its appearance about the eighteenth or twentieth year, and unites with the rest of the bone about the twenty-fifth year.

Articulations.—With the sternum, scapula, and cartilage of the first rib.

Attachment of Muscles.—To six: the Sterno-cleido-mastoid, Trapezius, Pectoralis major, Deltoid, Subclavius, and Sterno-hyoid.

Surface Form.—The clavicle can be felt throughout its entire length, even in persons who are very fat. Commencing at the inner end, the enlarged sternal extremity, where the bone projects above the upper margin of the sternum, can be felt, forming with the sternum and the rounded tendon of the Sterno-mastoid a V-shaped notch, the *pre-sternal notch*. Passing outward, the shaft of the bone can be felt immediately under the skin, with its convexity forward in the inner two-thirds, the surface partially obscured above and below by the attachments of the Sterno-mastoid and Pectoralis major muscles. In the outer third it forms a gentle curve backward, and terminates at the outer end in a somewhat enlarged extremity which articulates with the acromial process of the scapula. The direction of the clavicle is almost, if not quite, horizontal when the arm is lying quietly by the side, though in well-developed subjects it may incline a little upward at its outer end. Its direction is, however, very changeable with the varying movements of the shoulder-joint.

Surgical Anatomy.—The clavicle is the most frequently broken of any single bone in the body. This is due to the fact that it is much exposed to violence, and is the only bony connection between the upper limb and the trunk. The bone, moreover, is slender, and is very superficial. The bone may be broken by direct or indirect violence or by muscular action. The most common cause is, however, from indirect violence, and the bone then gives way at the junction of the outer with the inner two-thirds of the bone; that is to say at the junction of the two curves, for this is the weakest part of the bone. The fracture is generally oblique, and the displacement of the outer fragments is inward, away from the surface of the body; hence compound fracture of the clavicle is of rare occurrence. The inner fragment as a rule is little displaced. Beneath the bone the main vessels of the upper limb and the great nerve-cords of the brachial plexus lie on the first rib, and are liable to be wounded in fracture, especially in fracture from direct violence, when the force of the blow drives the broken ends inward. Fortunately, the Subclavius muscle is interposed between these structures and the clavicle, and this often protects them from injury.

The clavicle is not uncommonly the seat of sarcomatous tumors, rendering the operation of excision of the entire bone necessary. This is an operation of considerable difficulty and danger. It is best performed by exposing the bone freely, disarticulating at the acromial end, and turning it inward. The removal of the outer part is comparatively easy, but resection of the inner part is fraught with difficulty, the main danger being the risk of wounding the great veins which are in relation with its under surface.

The Scapula.

The *Scapula* (*σκαπὴν*, a spade) forms the back part of the shoulder girdle. It is a large, flat bone, triangular in shape, situated at the posterior aspect and side of

FIG. 94.—Left scapula, anterior surface, or venter.

the thorax, between the second and seventh, or sometimes the eighth, ribs, its internal border or base being about an inch from, and nearly, but not quite parallel with the spinous processes of the vertebræ, so that it is rather closer to them above than below. It presents for examination two surfaces, three borders, and three angles.

The *anterior surface, or venter* (Fig. 94), presents a broad concavity, the *sub-*

scapular fossa. It is marked, in the inner two-thirds, by several oblique ridges, which pass from behind outward and upward; the outer third is smooth. The oblique ridges give attachment to the tendinous intersections, and the surfaces between them to the fleshy fibres, of the Subscapularis muscle. The anterior third of the fossa, which is smooth, is covered by, but does not afford attachment to, the fibres of this muscle. The venter is separated from the internal border by a smooth, triangular margin at the superior and inferior angles, and in the interval between these by a narrow edge which is often deficient.

FIG. 95.—Left scapula. Posterior surface, or dorsum.

This marginal surface affords attachment throughout its entire extent to the Serratus magnus muscle. The subscapular fossa presents a transverse depression at its upper part, where the bone appears to be bent on itself, forming a considerable angle, called the *subscapular angle*, thus giving greater strength to the body of the bone from its arched form, while the summit of the arch serves to support the spine and acromion process. It is in this situation that the fossa is deepest, so that the thickest part of the Subscapularis muscle lies in a line perpendicular

to the plane of the glenoid cavity, and must consequently operate most effectively on the head of the humerus, which is contained in that cavity.

The **posterior surface**, or **dorsum** (Fig. 95), is arched from above downward, alternately concave and convex from side to side. It is subdivided unequally into two parts by the *spine*: the portion above the spine is called the *supraspinous fossa*, and that below it the *infraspinous fossa*.

The **supraspinous fossa**, the smaller of the two, is concave, smooth, and broader at the vertebral than at the humeral extremity. It affords attachment by its inner two-thirds to the Supraspinatus muscle.

The **infraspinous fossa** is much larger than the preceding; toward its vertebral margin a shallow concavity is seen at its upper part; its centre presents a prominent convexity, whilst toward the axillary border is a deep groove which runs from the upper toward the lower part. The inner two-thirds of this surface affords attachment to the Infraspinatus muscle; the outer third is only covered by it, without giving origin to its fibres. This surface is separated from the axillary border by an elevated ridge, which runs from the lower part of the glenoid cavity downward and backward to the posterior border, about an inch above the inferior angle. The ridge serves for the attachment of a strong aponeurosis which separates the Infraspinatus from the two Teres muscles. The surface of bone between this line and the axillary border is narrow in the upper two-thirds of its extent, and traversed near its centre by a groove for the passage of the dorsalis scapulæ vessels; it affords attachment to the Teres minor. Its lower third presents a broader, somewhat triangular surface, which gives origin to the Teres major, and over which the Latissimus dorsi glides; sometimes the latter muscle takes origin by a few fibres from this part. The broad and narrow portions of bone above alluded to are separated by an oblique line which runs from the axillary border, downward and backward, to meet the elevated ridge: to it is attached the aponeurosis separating the two Teres muscles from each other.

The **Spine** is a prominent plate of bone which crosses obliquely the inner four-fifths of the dorsum of the scapula at its upper part, and separates the supra- from the infraspinous fossa: it commences at the vertebral border by a smooth, triangular surface, over which the Trapezius glides, separated from the bone by a bursa, and, gradually becoming more elevated as it passes outward, terminates in the acromion process, which overhangs the shoulder-joint. The spine is triangular and flattened from above downward, its apex corresponding to the vertebral border, its base (which is directed outward) to the neck of the scapula. It presents two surfaces and three borders. Its *superior surface* is concave, assists in forming the supraspinous fossa, and affords attachment to part of the Supraspinatus muscle. Its *inferior surface* forms part of the infraspinous fossa, gives origin to part of the Infraspinatus muscle, and presents near its centre the orifice of a nutrient canal. Of the three borders, the *anterior* is attached to the dorsum of the bone; the *posterior*, or *crest* of the spine, is broad, and presents two lips and an intervening rough interval. To the superior lip is attached the Trapezius to the extent shown in the figure. A rough tubercle is generally seen occupying that portion of the spine which receives the insertion of the middle and inferior fibres of this muscle. To the inferior lip, throughout its whole length, is attached the Deltoid. The interval between the lips is also partly covered by the tendinous fibres of these muscles. The *external border*, or *base*, the shortest of the three, is slightly concave, its edge thick and round, continuous above with the under surface of the acromion process, below with the neck of the scapula. The narrow portion of bone external to this border, and separating it from the glenoid cavity, is called the *great scapular notch*, and serves to connect the supra- and infraspinous fossæ.

The **Acromion Process**, so called from forming the summit of the shoulder (*ἄκρον*, a summit; *ὤμος*, the shoulder), is a large and somewhat triangular or oblong process, flattened from behind forward, directed at first a little outward, and then curving forward and upward, so as to overhang the glenoid cavity. Its

upper surface, directed upward, backward, and outward, is convex, rough, and gives attachment to some fibres of the Deltoid, and in the rest of its extent it is subcutaneous. Its *under surface* is smooth and concave. Its *outer border* is thick and irregular, and presents three or four tubercles for the tendinous origins of the Deltoid muscle. Its *inner margin*, shorter than the outer, is concave, gives attachment to a portion of the Trapezius muscle, and presents about its centre a small oval surface for articulation with the acromial end of the clavicle. Its *apex*, which corresponds to the point of meeting of these two borders in front, is thin, and has attached to it the coraco-acromial ligament.

Borders.—Of the three borders of the scapula, the *superior* is the shortest and thinnest; it is concave and extends from the superior angle to the coracoid process. At its outer part is a deep, semicircular notch, the *suprascapular*, formed partly by the base of the coracoid process. This notch is converted into a foramen by the transverse ligament, and serves for the passage of the suprascapular nerve. Sometimes this foramen is entirely surrounded by bone. The adjacent margin of the superior border affords attachment to the Omo-hyoid muscle. The *external*, or *axillary*, *border*, is the thickest of the three. It commences above at the lower margin of the glenoid cavity, and inclines obliquely downward and backward to the inferior angle. Immediately below the glenoid cavity is a rough impression (the *infraglenoid tubercle*), about an inch in length, which affords attachment to the long head of the Triceps muscle; in front of this is a longitudinal groove, which extends as far as its lower third and affords origin to part of the Subscapularis muscle. The inferior third of this border, which is thin and sharp, serves for the attachment of a few fibres of the Teres major behind and of the Subscapularis in front. The *internal*, or *vertebral*, *border*, also named the *base*, is the longest of the three, and extends from the superior to the inferior angle of the bone. It is arched, intermediate in thickness between the superior and the external borders, and the portion of it above the spine is bent considerably outward, so as to form an obtuse angle with the lower part. The vertebral border presents an anterior lip, a posterior lip, and an intermediate space. The *anterior lip* affords attachment to the Serratus magnus; the *posterior lip*, to the Supraspinatus above the spine, the Infraspinatus below; the interval between the two lips, to the Levator anguli scapulæ above the triangular surface at the commencement of the spine, the Rhomboideus minor to the edge of that surface; the Rhomboideus major being attached by means of a fibrous arch connected above to the lower part of the triangular surface at the base of the spine, and below to the lower part of the posterior border.

Angles.—Of the three angles, the *superior*, formed by the junction of the superior and internal borders, is thin, smooth, rounded, somewhat inclined outward, and gives attachment to a few fibres of the Levator anguli scapulæ muscle. The *inferior* angle, thick and rough, is formed by the union of the vertebral and axillary borders, its outer surface affording attachment to the Teres major and frequently to a few fibres of the Latissimus dorsi. The *anterior* angle is the thickest part of the bone, and forms what is called the *head* of the scapula. The head presents a shallow, pyriform, articular surface, the *glenoid cavity* (γλήνη, a socket), whose longest diameter is from above downward, and its direction outward and forward. It is broader below than above; at its apex is a slight impression (*supraglenoid tubercle*), to which is attached the long tendon of the Biceps muscle. It is covered with cartilage in the recent state; and its margins, slightly raised, give attachment to a fibro-cartilaginous structure, the *glenoid ligament*, by which its cavity is deepened. The *neck* of the scapula is the slightly depressed surface which surrounds the head; it is more distinct on the posterior than on the anterior surface, and below than above. In the latter situation it has arising from it a thick prominence, the coracoid process.

The **Coracoid Process**, so called from its fancied resemblance to a crow's beak (κόραξ, a crow), is a thick, curved process of bone which arises by a broad base from the upper part of the neck of the scapula; it is directed at first upward and

inward, then, becoming smaller, it changes its direction and passes forward and outward. The ascending portion, flattened from before backward, presents in front a smooth, concave surface over which passes the Subscapularis muscle. The horizontal portion is flattened from above downward, its upper surface is convex and irregular, and gives attachment to the Pectoralis minor; its under surface is smooth; its inner border is rough, and gives attachment to the Pectoralis minor; its outer border is also rough for the coraco-acromial ligament, while the apex is embraced by the conjoined tendon of origin of the short head of the Biceps and of the Coraco-brachialis and gives attachment to the Costo-coracoid ligament. At the inner side of the root of the coracoid process is a rough impression for the attachment of the conoid ligament; and running from it obliquely forward and outward on the upper surface of the horizontal portion, an elevated ridge for the attachment of the trapezoid ligament.

FIG. 96.—Plan of the development of the scapula. By seven centres. The epiphyses (except one for the coracoid process) appear from fifteen to seventeen years, and unite between twenty-two and twenty-five years of age.

Structure.—In the head, processes, and all the thickened parts of the bone the scapula is composed of cancellous tissue, while in the rest of its extent it is composed of a thin layer of dense, compact tissue. The centre part of the supraspinous fossa and the upper part of the infra-spinous fossa, but especially the former, are usually so thin as to be semitransparent; occasionally the bone is found wanting in this situation, and the adjacent muscles come into contact.

Development (Fig. 96).—By *seven* or more centres: one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, and one for the inferior angle.

Ossification of the body of the scapula commences about the second month of fetal life by the formation of an irregular quadrilateral plate of bone immediately behind the glenoid cavity. This plate extends itself so as to form the chief part of the bone, the spine growing up from its posterior surface about the third month.

At birth a large part of the scapula is osseous, but the glenoid cavity, coracoid and acromion processes, the posterior border, and inferior angle are cartilaginous. From the fifteenth to the eighteenth month after birth ossification takes place in the middle of the coracoid process, which usually becomes joined with the rest of the bone at the time when the other centres make their appearance. Between the fourteenth and twentieth years ossification of the remaining centres takes place in quick succession, and in the following order: first, in the root of the coracoid process, in the form of a broad scale; secondly, near the base of the acromion process; thirdly, in the inferior angle and contiguous part of the posterior border; fourthly, near the extremity of the acromion; fifthly, in the posterior border. The acromion process, besides being formed of two separate nuclei, has its base formed by an extension into it of the centre of ossification which belongs to the spine, the extent of which varies in different cases. The two separate nuclei unite, and then join with the extension from the spine. These various epiphyses become joined to the bone between the ages of twenty-two and twenty-five years. Sometimes failure of union between the acromion process and spine occurs, the junction being effected by fibrous tissue or by an imperfect articulation; in some cases of supposed fracture of the acromion with ligamentous union it is probable that the detached segment was never united to the rest of the bone. The upper third of the glenoid cavity is usually ossified from a separate centre (subcoracoid) which makes its appearance between the tenth and eleventh years. Very often, in addition, an epiphysis appears for the lower part of the glenoid cavity.

Articulations.—With the humerus and clavicle.

Attachment of Muscles.—To seventeen: to the anterior surface, the Subscapularis; posterior surface, Supraspinatus, Infraspinatus; spine, Trapezius, Deltoid; superior border, Omo-hyoid; vertebral border, Serratus magnus, Levator anguli scapulae, Rhomboideus minor and major; axillary border, Triceps, Teres minor, Teres major; apex of glenoid cavity, long head of the Biceps; coracoid process, short head of the Biceps, Coraco-brachialis, Pectoralis minor; and to the inferior angle occasionally a few fibres of the Latissimus dorsi.

Surface Form.—The only parts of the scapula which are truly subcutaneous are the spine and acromion process, but, in addition to these, the coracoid process, the internal or vertebral border and inferior angle, and, to a less extent, the axillary border, may be defined. The acromion process and spine of the scapula are easily felt throughout their entire length, forming, with the clavicle, the arch of the shoulder. The acromion can be ascertained to be connected to the clavicle at the acromio-clavicular joint by running the finger along it, its position being often indicated by an irregularity or bony outgrowth from the clavicle close to the joint. The acromion can be felt forming the point of the shoulder, and from this can be traced backward to join the spine of the scapula. The place of junction is usually denoted by a prominence, which is sometimes called the angle. From here the spine can be felt as a prominent ridge of bone, marked on the surface as an oblique depression, which becomes less and less distinct, and terminates a little external to the spinous processes of the vertebræ. Its termination is usually indicated by a slight dimple in the skin on a level with the interval between the third and fourth dorsal spines. Below this point the vertebral border of the scapula may be traced, running downward and outward, and thus diverging from the vertebral spines, to the inferior angle of the bone, which can be recognized, although covered by the Latissimus dorsi muscle. From this angle the axillary border can usually be traced through this thick muscular covering, forming, with the muscles, the posterior fold of the axilla. The coracoid process may be felt about an inch below the junction of the middle and outer third of the clavicle. Here it is covered by the anterior border of the deltoid and lies a little to the outer side of a slight depression which corresponds to the interval between the Pectoralis major and Deltoid muscles. When the arms are hanging by the side, the upper angle of the scapula corresponds to the upper border of the second rib or the interval between the first and second dorsal spines, the inferior angle to the upper border of the eighth rib or the interval between the seventh and eighth dorsal spines.

Surgical Anatomy.—Fractures of the body of the scapula are rare, owing to the mobility of the bone, the thick layer of muscles by which it is encased on both surfaces, and the elasticity of the ribs on which it rests. Fracture of the neck of the bone is also uncommon. The most frequent course of the fracture is from the suprascapular notch to the infraglenoid tubercle, and it derives its principal interest from its simulation to a subglenoid dislocation of the humerus. The diagnosis can be made by noting the alteration in the position of the coracoid process. A fracture of the neck external to, and not including, the coracoid process is said to occur, but it is exceedingly doubtful whether such an accident ever takes place. The acromion process is more frequently broken than any other part of the bone, and there is some-

times, in young subjects, a separation of the epiphysis. It is believed that many of the cases of supposed fracture of the acromion, with fibrous union, which have been found on post-mortem examination are really cases of imperfectly united epiphysis. Sir Astley Cooper believed that most fractures of this bone united by fibrous tissue, and the cause of this mode of union was the difficulty there was in keeping the fractured ends in constant apposition. The coracoid process is occasionally broken off, either from direct violence or perhaps, rarely, from muscular action.

Tumors of various kinds grow from the scapula. Of the innocent form of tumors probably the osteomata are the most common. When it grows from the venter of the scapula, as it sometimes does, it is of the compact variety, such as usually grows from membrane-formed bones, as the bones of the skull. This would appear to afford evidence that this portion of the bone is formed from membrane, and not, like the rest of the bone, from cartilage. Sarcomatous tumors sometimes grow from the scapula, and may necessitate removal of the bone, with or without amputation of the upper limb. The bone may be excised by a T-shaped incision, and, the flaps being reflected, the removal is commenced from the posterior or vertebral border, so that the subscapular vessels which lie along the axillary border are among the last structures divided, and can be at once secured.

THE ARM.

The **arm** is that portion of the upper extremity which is situated between the shoulder and the elbow. Its skeleton consists of a single bone, the humerus.

The Humerus.

The **Humerus** is the longest and largest bone of the upper extremity; it presents for examination a shaft and two extremities.

The **Upper Extremity** presents a large, rounded *head*, joined to the shaft by a constricted portion, called the *neck*, and two other eminences, the *greater* and *lesser tuberosities* (Fig. 97).

The *head*, nearly hemispherical in form,¹ is directed upward, inward, and a little backward, and articulates with the glenoid cavity of the scapula; its surface is smooth and coated with cartilage in the recent state. The circumference of its articular surface is slightly constricted, and is termed the *anatomical neck*, in contradistinction to the constriction which exists below the tuberosities. The latter is called the *surgical neck*, from its often being the seat of fracture. It should be remembered, however, that fracture of the *anatomical neck* does sometimes, though rarely, occur.

The *anatomical neck* is obliquely directed, forming an obtuse angle with the shaft. It is more distinctly marked in the lower half of its circumference than in the upper half, where it presents a narrow groove, separating the head from the tuberosities. Its circumference affords attachment to the capsular ligament and is perforated by numerous vascular foramina.

The *greater tuberosity* is situated on the outer side of the head and lesser tuberosity. Its upper surface is rounded and marked by three flat facets, separated by two slight ridges: the highest facet gives attachment to the tendon of the Supraspinatus; the middle one, to the Infraspinatus; the inferior facet and the shaft of the bone below it, to the Teres minor. The outer surface of the great tuberosity is convex, rough, and continuous with the outer side of the shaft.

The *lesser tuberosity* is more prominent, although smaller than the greater: it is situated in front of the head, and is directed inward and forward. Its summit presents a prominent facet for the insertion of the tendon of the Subscapularis muscle. The tuberosities are separated from one another by a deep groove, the *bicipital groove*, so called from its lodging the long tendon of the Biceps muscle, with which runs a branch of the anterior circumflex artery. It commences above between the two tuberosities, passes obliquely downward and a little inward, and terminates at the junction of the upper with the middle third of the bone. It is deep and narrow at the commencement, and becomes shallow and a little broader as it descends. Its borders are called, respectively, the anterior

¹ Though the head is nearly hemispherical in form, its margin, as Sir G. Humphry has shown, is by no means a true circle. Its greatest measurement is from the top of the bicipital groove in a direction downward, inward, and backward. Hence it follows that the greatest elevation of the arm can be obtained by rolling the articular surface in this direction—that is to say, obliquely upward, outward, and forward.

FIG. 97.—Left humerus. Anterior view.

and posterior *bicipital ridges*, and form the upper part of the anterior and internal

borders of the shaft of the bone. In the recent state it is covered with a thin layer of cartilage, lined by a prolongation of the synovial membrane of the shoulder-joint, and receives the tendon of insertion of the *Latissimus dorsi* muscle.

The **Shaft** of the humerus is almost cylindrical in the upper half of its extent, prismatic and flattened below, and presents three borders and three surfaces for examination.

The **anterior border** runs from the front of the great tuberosity above to the coronoid depression below, separating the internal from the external surface. Its upper part is very prominent and rough, and forms the outer lip of the bicipital groove. It is sometimes called the *anterior bicipital* or *pectoral ridge*, and serves for the attachment of the tendon of the *Pectoralis major*. About its centre it forms the anterior boundary of the rough deltoid impression; below, it is smooth and rounded, affording attachment to the *Brachialis anticus*.

The **external border** runs from the back part of the greater tuberosity to the external condyle, and separates the external from the posterior surface. It is rounded and indistinctly marked in its upper half, serving for the attachment of the lower part of the insertion of the *Teres minor*, and below this of the external head of the *Triceps* muscle; its centre is traversed by a broad but shallow, oblique depression, the *musculo-spiral groove*; its lower part is marked by a prominent, rough margin, a little curved from behind forward, the *external supracondylar ridge*, which presents an anterior lip for the attachment of the *Supinator longus* above and *Extensor carpi radialis longior* below, a posterior lip for the *Triceps*, and an intermediate space for the attachment of the external intermuscular septum.

The **internal border** extends from the lesser tuberosity to the internal condyle. Its upper third is marked by a prominent ridge, forming the posterior lip of the bicipital groove, and gives attachment to the tendon of the *Teres major*. About its centre is an impression for the attachment of the *Coraco-brachialis*, and just below this is seen the entrance of the nutrient canal, directed downward. Sometimes there is a second canal, situated at the commencement of the musculo-spiral groove, for a nutrient artery derived from the superior profunda branch of the brachial artery. The inferior third of this border is raised into a slight ridge, the *internal supracondylar ridge*, which becomes very prominent below; it presents an anterior lip for the attachment of the *Brachialis anticus*, a posterior lip for the internal head of the *Triceps*, and an intermediate space for the attachment of the internal intermuscular septum.

The **external surface** is directed outward above, where it is smooth, rounded, and covered by the *Deltoid* muscle; forward and outward below, where it is slightly concave from above downward, and gives origin to part of the *Brachialis anticus* muscle. About the middle of this surface is seen a rough, triangular impression for the insertion of the *Deltoid* muscle; and below it the musculo-spiral groove, directed obliquely from behind, forward and downward, and transmitting the musculo-spiral nerve and superior profunda artery.

The **internal surface**, less extensive than the external, is directed inward above, forward and inward below; at its upper part it is narrow and forms the floor of the bicipital groove: to it is attached the *Latissimus dorsi*. The middle part of this surface is slightly rough for the attachment of some of the fibres of the tendon of insertion of the *Coraco-brachialis*; its lower part is smooth, concave from above downward, and gives attachment to the *Brachialis anticus* muscle.¹

¹ A small, hook-shaped process of bone, the *supracondylar process*, varying from $\frac{1}{10}$ to $\frac{1}{4}$ of an inch in length, is not infrequently found projecting from the inner surface of the shaft of the humerus two inches above the internal condyle. It is curved downward, forward, and inward, and its pointed extremity is connected to the internal border, just above the inner condyle, by a ligament or fibrous band, which gives origin to a portion of the *Pronator radii teres*; through the arch completed by this fibrous band the median nerve and brachial artery pass when these structures deviate from their usual course. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery in cases of high division of the brachial. A well-marked groove is usually found behind the process in which the nerve and artery are lodged. This space is analogous to the supracondylar foramen in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region. A detailed account of this process is given by Dr. Struthers, in his *Anatomical and Physiological Observations*, p. 202. An accessory portion of the *Coracobrachialis* muscle is frequently connected with this process, according to Mr. J. Wood (*Journal of Anat. and Phys.*, No. 1, Nov., 1866, p. 47).

The **posterior surface** (Fig. 98) appears somewhat twisted, so that its upper part is directed a little inward, its lower part backward and a little outward. Nearly the whole of this surface is covered by the external and internal heads of the Triceps, the former of which is attached to its upper and outer part, the latter to its inner and back part, the two being separated by the musculo-spiral groove.

The **Lower Extremity** is flattened from before backward, and curved slightly forward; it terminates below in a broad, articular surface which is divided into two parts by a slight ridge. Projecting on either side are the external and internal condyles. The articular surface extends a little lower than the condyles, and is curved slightly forward, so as to occupy the more anterior part of the bone; its greatest breadth is in the transverse diameter, and it is obliquely directed, so that its inner extremity occupies a lower level than the outer. The outer portion of the articular surface presents a smooth, rounded eminence, which has received the name of the *capitellum*, or *radial head* of the humerus; it articulates with the cup-shaped depression on the head of the radius, and is limited to the front and lower part of the bone, not extending as far back as the other portion of the articular surface. On the inner side of this eminence is a shallow groove, in which is received the inner margin of the head of the radius. Above the front part of the capitellum is a slight depression, the *radial fossa*, which receives the anterior border of the head of the radius when the forearm is flexed. The inner portion of the articular surface, the *trochlea*, presents a deep depression between two well-marked borders. This surface is convex from before backward, concave from side to side, and occupies the anterior, lower, and posterior parts of the bone. The external border, less prominent than the internal, corresponds to the interval between the radius and the ulna. The internal border is thicker, more prominent, and consequently of greater length, than the external. The grooved portion of the articular surface fits accurately within the greater sigmoid cavity of the ulna: it is broader and deeper on the posterior than on the anterior aspect of the bone, and is inclined obliquely from behind forward and from without inward. Above the front part of the trochlear surface is seen a smaller depression, the *coronoid fossa*, which receives the coronoid process of the ulna during flexion of the forearm. Above the back part of the trochlear surface is a deep, triangular depression, the *olecranon fossa*, in which is received the summit of the olecranon process in extension of

FIG. 98.—Left humerus. Posterior surface.

the forearm. These fossæ are separated from one another by a thin, transparent lamina of bone, which is sometimes perforated, forming the *supratrochlear foramen*;

their upper margins afford attachment to the anterior and posterior ligaments of the elbow-joint, and they are lined, in the recent state, by the synovial membrane of this articulation. The articular surfaces, in the recent state, are covered with a thin layer of cartilage. The external condyle (*epicondyle*) is a small, tubercular eminence, less prominent than the internal, curved a little forward, and giving attachment to the external lateral ligament of the elbow-joint, and to a tendon common to the origin of some of the extensor and supinator muscles. The internal condyle (*epitrochlea*), larger and more prominent, and therefore more liable to fracture, than the external, is directed a little backward: it gives attachment to the internal lateral ligament, to the Pronator radii teres, and to a tendon common to the origin of some of the flexor muscles of the forearm. The ulnar nerve runs in a groove at the back of the internal condyle, or between it and the olecranon process. These condyles are directly continuous above with the external and internal supracondylar ridges.

Structure.—The extremities consist of cancellous tissue, covered with a thin compact layer; the shaft is composed of a cylinder of compact tissue, thicker at the centre than at the extremities, and hollowed out

Epiphyses of head and tuberosities blend at 5th year, and unite with shaft at 20th year.

FIG. 99.—Plan of the development of the humerus. By seven centres.

by a large medullary canal, which extends along its whole length.

Development.—By *seven*, or occasionally *eight*, centres (Fig. 99), one for the shaft, one for the head, one for the tuberosities, one for the radial head, one for the trochlear portion of the articular surface, and one for each condyle. The nucleus for the shaft appears near the centre of the bone in the eighth week, and soon extends toward the extremities. At birth the humerus is ossified nearly in its whole length, the extremities remaining cartilaginous. During the first year, sometimes before birth, ossification commences in the head of the bone, and during the third year the centre for the tuberosities makes its appearance, usually by a single ossific point, but sometimes, according to Béclard, by one for each tuberosity, that for the lesser being small and not appearing until the fifth year. By the sixth year the centres for the head and tuberosities have increased in size and become joined, so as to form a single large epiphysis.

The lower end of the humerus is developed in the following manner: At the end of the second year ossification commences in the capitellum, and from this point extends inward, so as to form the chief part of the articular end of the bone, the centre for the inner part of the trochlea not appearing until about the age of twelve. Ossification commences in the internal condyle about the fifth year, and in the external one not until about the thirteenth or fourteenth year. About sixteen or seventeen years the outer condyle and both portions of the articulating surface (having already joined) unite with the shaft; at eighteen years the inner condyle becomes joined; while the upper epiphysis, although the first formed, is not united until about the twentieth year.

Articulations.—With the glenoid cavity of the scapula and with the ulna and radius.

Attachment of Muscles.—To twenty-four: to the greater tuberosity, the Supraspinatus, Infraspinatus, and Teres minor; to the lesser tuberosity, the Subscapularis; to the anterior bicipital ridge, the Pectoralis major; to the posterior bicipital ridge, the Teres major; to the bicipital groove, the Latissimus dorsi; to the shaft, the Deltoid, Coraco-brachialis, Brachialis anticus, external and internal heads of the Triceps; to the internal condyle, the Pronator radii teres, and common tendon of the Flexor carpi radialis, Palmaris longus, Flexor sublimis digitorum, and Flexor carpi ulnaris; to the external condyloid ridge, the Supinator longus and Extensor carpi radialis longior; to the external condyle, the common tendon of the Extensor carpi radialis brevis, Extensor communis digitorum, Extensor minimi digiti, Extensor carpi ulnaris, and Supinator brevis; to the back of the external condyle, the Anconeus.

Surface Form.—The humerus is almost entirely clothed by the muscles which surround it, and the only parts of this bone which are strictly subcutaneous are small portions of the internal and external condyles. In addition to these, the tuberosities and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these the greater tuberosity forms the most prominent bony point of the shoulder, extending beyond the acromion process and covered by the Deltoid muscle. It influences materially the surface form of the shoulder. It is best felt while the arm is lying loosely by the side; if the arm be raised, it recedes from under the finger. The lesser tuberosity, directed forward and inward, is to be felt to the inner side of the greater tuberosity, just below the acromio-clavicular joint. Between the two tuberosities lies the bicipital groove. This can be defined by placing the finger and making firm pressure just internal to the greater tuberosity; then, by rotating the humerus, the groove will be felt to pass under the finger as the bone is rotated. With the arm abducted from the side, by pressing deeply in the axilla the lower part of the head of the bone is to be felt. On each side of the elbow-joint, and just above it, the internal and external condyles of the bone are to be felt. Of these the internal is the more prominent, but the ridge passing upward from it, the internal condyloid ridge, is much less marked than the external, and, as a rule, is not to be felt. Occasionally, however, we find along this border the hook-shaped process mentioned above. The external condyle is most plainly to be seen during semiflexion of the forearm, and its position is indicated by a depression between the attachment of the adjacent muscles. From it is to be felt a strong bony ridge running up the outer border of the shaft of the bone. This is the external supracondylar ridge; it is concave forward, and corresponds with the curved direction of the lower extremity of the humerus.

Surgical Anatomy.—There are several points of surgical interest connected with the humerus. First, as regards its development. The upper end, though the first to ossify, is the last to join the shaft, and the length of the bone is mainly due to growth from this upper epiphysis. Hence, in cases of amputation of the arm in young subjects the humerus continues to grow considerably, and the end of the bone which immediately after the operation was covered with a thick cushion of soft tissue, begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of a couple of inches or so of the bone, and even after this operation a recurrence of the conical stump may take place.

There are several points of surgical interest in connection with fractures. First, as regard their causation: the bone may be broken by direct or indirect violence like the other long bones, but, in addition to this, it is probably more frequently fractured by muscular action than any other of this class of bone in the body. It is usually the shaft, just below the insertion of the Deltoid, which is thus broken. I have seen the accident happen from throwing a stone, and in an apparently healthy adult from cutting a piece of hard "cake tobacco" on a table. In this latter case there was no disease of the bone that could be discovered. Fractures of the upper end may take place through the anatomical neck, through the surgical neck, or separation of the greater tuberosity may occur. Fracture of the anatomical neck is a very rare accident; in fact, it is doubted by some whether it ever occurs. These fractures are usually considered to be intracapsular, but they are probably partly within and partly without the capsule, as the lower part of the capsule is inserted some little distance below the anatomical neck, while the upper part is attached to it. They may be impacted or non-impacted. In most cases there is little or no displacement on account of the capsule, in whole or in part, remaining attached to the lower fragment. But occasionally a very remarkable alteration in position takes place; the upper fragment turns on its own axis, so that the cartilaginous surface of the head rests against the upper end of the lower fragment. When the fractured end is entirely separated from all its surroundings, its vascular supply must be entirely cut off, and one would expect it, theoretically, to necrose. But this must be exceedingly rare, for Gurlt was unable to find a single authenticated case recorded. Separation of the upper epiphysis of the humerus sometimes occurs in the young subject, and is marked by a characteristic deformity by which the lesion may be at once recognized. This consists in the presence of an abrupt projection at the front of the joint some short distance below the coracoid process, caused by the upper end of the lower fragment. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower than in the upper part of the bone. The points of interest in con-

nection with these fractures are—(1) that the musculo-spiral nerve may be injured as it lies in the groove on the bone, or may become involved in the callus which is subsequently thrown out; and (2) the frequency of non-union. This is believed to be more common in the humerus than in any other bone, and various causes have been assigned for it. It would seem most probably to be due to the difficulty that there is in fixing the shoulder-joint and the upper fragment, and possibly the elbow-joint and lower fragment also. Other causes which have been assigned for the non-union are: (1) that in attempting passive motion of the elbow-joint to overcome any rigidity which may exist, the movement does not take place at the articulation, but at the seat of fracture; or that the patient, in consequence of the rigidity of the elbow, in attempting to flex or extend the forearm moves the fragment and not the joint. (2) The presence of small portions of muscular tissue between the broken ends. (3) Want of support to the elbow, so that the weight of the arm tends to drag the lower fragment away from the upper. An important distinction to make in fractures of the lower end of the humerus is between those that involve the joint and those which do not; the former always serious, as they may lead to impairment of the utility of the limb. They include the T-shaped fracture and oblique fractures which involve the articular surface. The fractures which do not involve the joint are the transverse above the condyles and the so-called epitrochlear fracture, when the tip of the internal condyle has broken off, generally from direct violence.

Under the head of separation of the epiphysis two separate injuries have been described. One where the whole of the four ossific centres which form the lower extremity of the bone are separated from the shaft; and secondly, where the articular portion is alone separated, the two condyles remaining attached to the shaft of the bone. The epiphysal line between the shaft and lower end runs across the bone just above the tips of the condyles, a point to be borne in mind in performing the operation of excision.

Tumors originating from the humerus are of frequent occurrence. A not uncommon place for a chondroma to grow from is the shaft of the bone somewhere in the neighborhood of the insertion of the deltoid. Sarcomata frequently grow from this bone.

THE FOREARM.

The **Forearm** is that portion of the upper extremity which is situated between the elbow and the wrist. Its skeleton is composed of two bones, the ulna and radius.

The Ulna.

The **Ulna** (Figs. 100, 101), so called from its forming the elbow (*ὠλένη*), is a long bone, prismatic in form, placed at the inner side of the forearm, parallel with the radius. It is the larger and longer of the two bones. Its upper extremity, of great thickness and strength, forms a large part of the articulation of the elbow-joint; it diminishes in size from above downward, its lower extremity being very small, and excluded from the wrist-joint by the interposition of an interarticular fibro-cartilage. It is divisible into a shaft and two extremities.

The **Upper Extremity**, the strongest part of the bone, presents for examination two large, curved processes, the Olecranon process and the Coronoid process; and two concave, articular cavities, the greater and lesser sigmoid cavities.

The **Olecranon Process** (*ὠλένη*, elbow; *κρανίον*, head) is a large, thick, curved eminence situated at the upper and back part of the ulna. It is curved forward at the summit so as to present a prominent tip which is received into the olecranon fossa in extension of the forearm; its base being contracted where it joins the shaft. This is the narrowest part of the upper end of the ulna, and, consequently, the most usual seat of fracture. The posterior surface of the olecranon, directed backward, is triangular, smooth, subcutaneous, and covered by a bursa. Its upper surface is of a quadrilateral form, marked behind by a rough impression for the attachment of the Triceps muscle; and in front, near the margin, by a slight transverse groove for the attachment of part of the posterior ligament of the elbow-joint. Its interior surface is smooth, concave, covered with cartilage in the recent state, and forms the upper and back part of the great sigmoid cavity. The lateral borders present a continuation of the same groove that was seen on the margin of the superior surface; they serve for the attachment of ligaments; viz., the back part of the internal lateral ligament internally, the posterior ligament externally. To the inner border is also attached a part of the Flexor carpi ulnaris, while to the outer border is attached the Anconeus.

FIG. 100.—Bones of the left forearm. Anterior surface.

The **Coronoid Process** (*χορώνη*, anything hooked like a crow's beak) is a triangular eminence of bone which projects horizontally forward from the upper and front part of the ulna. Its base is continuous with the shaft, and of considerable strength; so much so that fracture of it is an accident of rare occurrence. Its apex is pointed, slightly curved upward, and received into the coronoid depression of the humerus in flexion of the forearm. Its upper surface is smooth, concave, and forms the lower part of the greater sigmoid cavity. The under surface is concave, and marked internally by a rough impression for the insertion of the *Brachialis anticus*. At the junction of this surface with the shaft is a rough eminence, the *tubercle of the ulna*, for the attachment of the oblique ligament. Its outer surface presents a narrow, oblong, articular depression, the *lesser sigmoid cavity*. The inner surface, by its prominent, free margin, serves for the attachment of part of the internal lateral ligament. At the front part of this surface is a small, rounded eminence for the attachment of one head of the *Flexor sublimis digitorum*; behind the eminence, a depression for part of the origin of the *Flexor profundus digitorum*; and, descending from the eminence, a ridge which gives attachment to one head of the *Pronator radii teres*. Generally, the *Flexor longus pollicis* has an origin from the lower part of the coronoid process by a rounded bundle of muscular fibres.

The **Greater Sigmoid Cavity**, so called from its resemblance to the old shape of the Greek letter Σ, is a semilunar depression of large size, formed by the olecranon and coronoid processes, and serving for articulation with the trochlear surface of the humerus. About the middle of either lateral border of this cavity is a notch which contracts it somewhat, and serves to indicate the junction of the two processes of which it is formed. The cavity is concave from above downward, and divided into two lateral parts by a smooth, elevated ridge which runs from the summit of the olecranon to the tip of the coronoid process. Of these two portions, the internal is the larger, and is slightly concave transversely; the external portion is convex above, slightly concave below. The articular surface, in the recent state, is covered with a thin layer of cartilage.

The **Lesser Sigmoid Cavity** is a narrow, oblong, articular depression, placed on the outer side of the coronoid process, and receives the lateral articular surface of the head of the radius. It is concave from before backward, and its extremities, which are prominent, serve for the attachment of the orbicular ligament. In the recent state it is covered with a thin layer of cartilage.

The **Shaft**, at its upper part, is prismatic in form, and curved from behind forward and from without inward, so as to be convex behind and externally; its central part is quite straight; its lower part rounded, smooth, and bent a little outward, it tapers gradually from above downward, and presents for examination three borders and three surfaces.

The **anterior border** commences above at the prominent inner angle of the coronoid process, and terminates below in front of the styloid process. It is well marked above, smooth and rounded in the middle of its extent, and affords attachment to the *Flexor profundus digitorum*: its lower fourth, marked off from the rest of the border by the commencement of an oblique ridge on the anterior surface, serves for the attachment of the *Pronator quadratus*. It separates the anterior from the internal surface.

The **posterior border** commences above at the apex of the triangular subcutaneous surface at the back part of the olecranon, and terminates below at the back part of the styloid process; it is well marked in the upper three-fourths, and gives attachment to the aponeurosis common to the *Flexor carpi ulnaris*, the *Extensor carpi ulnaris*, and the *Flexor profundus digitorum* muscles; its lower fourth is smooth and rounded. This border separates the internal from the posterior surface.

The **external or interosseous border** commences above by the union of two lines, which converge one from each extremity of the lesser sigmoid cavity, enclosing between them a triangular space for the attachment of part of the *Supinator brevis*,

and terminates below at the middle of the head of the ulna. Its two middle fourths are very prominent; its lower fourth is smooth and rounded. This border gives attachment to the interosseous membrane, and separates the anterior from the posterior surface.

The **anterior surface**, much broader above than below, is concave in the upper three-fourths of its extent, and affords attachment to the Flexor profundus digitorum; its lower fourth, also concave, is covered by the Pronator quadratus. The lower fourth is separated from the remaining portion of the bone by a prominent ridge, directed obliquely from above downward and inward; this ridge (the *oblique* or *Pronator ridge*) marks the extent of attachment of the Pronator quadratus. At the junction of the upper with the middle third of the bone is the nutrient canal, directed obliquely upward and inward.

The **posterior surface**, directed backward and outward, is broad and concave above, somewhat narrower and convex in the middle of its course, narrow, smooth, and rounded below. It presents, above, an oblique ridge, which runs from the posterior extremity of the lesser sigmoid cavity, downward to the posterior border; the triangular surface above this ridge receives the insertion of the Anconeus muscle, whilst the upper part of the ridge itself affords attachment to the Supinator brevis. The surface of bone below this is subdivided by a longitudinal ridge, sometimes called the *perpendicular line*, into two parts: the internal part is smooth, and covered by the Extensor carpi ulnaris; the external portion, wider and rougher, gives attachment from above downward to part of the Supinator brevis, the Extensor ossis metacarpi pollicis, the Extensor longus pollicis, and the Extensor indicis muscles.

The **internal surface** is broad and concave above, narrow and convex below. It gives attachment by its upper three-fourths to the Flexor profundus digitorum muscle: its lower fourth is subcutaneous.

The **Lower Extremity** of the ulna is of small size, and excluded from the articulation of the wrist-joint.

It presents for examination two eminences, the outer and larger of which is a rounded, articular eminence, termed the *head* of the ulna, the inner, narrower and more projecting, is a non-articular eminence, the *styloid process*. The *head* presents an articular facet, part of which, of an oval or semilunar form, is directed downward, and articulates with the upper surface of the interarticular fibro-cartilage which separates it from the wrist-joint; the remaining portion, directed outward, is narrow, convex, and received into the sigmoid cavity of the radius. The *styloid process* projects from the inner and back part of the bone, and descends a little lower than the head, terminating in a rounded summit, which affords attachment to the internal lateral ligament of the wrist. The head is separated from the styloid process by a depression for the attachment of the triangular interarticular fibro-cartilage; and behind, by a shallow groove for the passage of the tendon of the Extensor carpi ulnaris.

Structure.—Similar to that of the other long bones.

Development.—By three centres: one for the shaft, one for the inferior extremity, and one for the olecranon (Fig. 102). Ossification commences near the middle of the shaft about the eighth week, and soon extends through the greater part of the bone. At birth the ends are cartilaginous. About the fourth year a separate osseous nucleus appears in the middle of the head, which soon extends into the styloid process. About the tenth year ossific matter appears in the olecranon near its extremity, the chief part of this

FIG. 102.—Plan of the development of the ulna. By three centres.

process being formed from an extension of the shaft of the bone into it. At about the sixteenth year the upper epiphysis becomes joined, and at about the twentieth year the lower one.

Articulations.—With the humerus and radius.

Attachment of Muscles.—To sixteen: to the olecranon, the Triceps, Anconeus, and one head of the Flexor carpi ulnaris. To the coronoid process, the Brachialis anticus, Pronator radii teres, Flexor sublimis digitorum, and Flexor profundus digitorum; generally also the Flexor longus pollicis. To the shaft, the Flexor profundus digitorum, Pronator quadratus, Flexor carpi ulnaris, Extensor carpi ulnaris, Anconeus, Supinator brevis, Extensor ossis metacarpi pollicis, Extensor longus pollicis, and Extensor indicis.

Surface Form.—The most prominent part of the ulna on the surface of the body is the olecranon process, which can always be felt at the back of the elbow-joint. When the forearm is flexed, the upper quadrilateral surface can be felt, directed backward; during extension it recedes into the olecranon fossa, and the contracting fibres of the triceps prevent its being perceived. At the back of the olecranon is the smooth, triangular, subcutaneous surface, which below is continuous with the posterior border of the shaft of the bone, and felt in every position of the forearm. During extension the upper border of the olecranon is slightly above the level of the internal condyle, and the process itself is nearer to this condyle than the outer one. Running down the back of the forearm, from the apex of the triangular surface which forms the posterior surface of the olecranon, is a prominent ridge of bone, the posterior border of the ulna. This is to be felt throughout the entire length of the shaft of the bone, from the olecranon above to the styloid process below. As it passes down the forearm it pursues a sinuous course and inclines to the inner side, so that, though it is situated in the middle of the back of the limb above, it is on the inner side of the wrist at its termination. It becomes rounded off in its lower third, and may be traced below to the small, subcutaneous surface of the styloid process. Internal to this border the lower fourth of the inner surface is to be felt. The styloid process is to be felt as a prominent tubercle of bone, continuous above with the posterior subcutaneous border of the ulna, and terminating below in a blunt apex, which lies a little internal and behind, but on a level with, the wrist-joint. The styloid process is best felt when the hand is in the same line as the bones of the forearm, and in a position midway between supination and pronation. If the forearm is pronated while the finger is placed on the process, it will be felt to recede, and another prominence of bone will appear just behind and above it. This is the head of the ulna, which articulates with the lower end of the radius and the triangular interarticular fibro-cartilage, and now projects between the tendons of the Extensor carpi ulnaris and the Extensor minimi digiti muscles.

The Radius.

The Radius (*radius*, a ray, or spoke of a wheel) is situated on the outer side of the forearm, lying side by side with the ulna, which exceeds it in length and size. (Figs. 100 and 101.) Its upper end is small, and forms only a small part of the elbow-joint; but its lower end is large, and forms the chief part of the wrist. It is one of the long bones, prismatic in form, slightly curved longitudinally, and, like other long bones, has a shaft and two extremities.

The **Upper Extremity** presents a head, neck, and tuberosity. The *head* is of a cylindrical form, depressed on its upper surface into a shallow cup which articulates with the capitellum or radial head of the humerus. In the recent state it is covered with a layer of cartilage which is thinnest at its centre. Around the circumference of the head is a smooth, articular surface, broad internally where it articulates with the lesser sigmoid cavity of the ulna; narrow in the rest of its circumference, where it rotates within the orbicular ligament. It is coated with cartilage in the recent state. The head is supported on a round, smooth, and constricted portion of bone, called the *neck*, which presents, behind, a slight ridge, for the attachment of part of the Supinator brevis. Beneath the neck, at the inner and front aspect of the bone, is a rough eminence, the *bicipital tuberosity*. Its surface is divided into two parts by a vertical line—a posterior, rough portion, for the insertion of the tendon of the Biceps muscle; and an anterior, smooth portion, on which a bursa is interposed between the tendon and the bone.

The **Shaft** of the bone is prismoid in form, narrower above than below, and slightly curved, so as to be convex outward. It presents three surfaces, separated by three borders.

The **anterior border** extends from the lower part of the tuberosity above to the anterior part of the base of the styloid process below. It separates the anterior from the external surface. Its upper third is very prominent; and from its oblique direction, downward and outward, has received the name of the *oblique line of the radius*. It gives attachment externally to the Supinator brevis, internally to the Flexor longus pollicis, and between these to the Flexor sublimis digitorum. The middle third of the anterior border is indistinct and rounded. Its lower fourth is sharp, prominent, affords attachment to the Pronator quadratus and to the posterior annular ligament of the wrist, and terminates in a small tubercle, into which is inserted the tendon of the Supinator longus.

The **posterior border** commences above at the back part of the neck of the radius, and terminates below at the posterior part of the base of the styloid process; it separates the posterior from the external surface. It is indistinct above and below, but well marked in the middle third of the bone.

The **internal or interosseous border** commences above at the back part of the tuberosity, where it is rounded and indistinct, becomes sharp and prominent as it descends, and at its lower part divides into two ridges, which descend to the anterior and posterior margins of the sigmoid cavity. This border separates the anterior from the posterior surface, and has the interosseous membrane attached to it throughout the greater part of its extent.

The **anterior surface** is concave for its upper three-fourths, and gives attachment to the Flexor longus pollicis muscle; it is broad and flat for its lower fourth, and gives attachment to the Pronator quadratus. A prominent ridge limits the attachment of the Pronator quadratus below, and between this and the inferior border is a triangular rough surface for the attachment of the anterior ligament of the wrist-joint. At the junction of the upper and middle third of this surface is the nutrient foramen, which is directed obliquely upward.

The **posterior surface** is rounded, convex, and smooth in the upper third of its extent, and covered by the Supinator brevis muscle. Its middle third is broad, slightly concave, and gives attachment to the Extensor ossis metacarpi pollicis above, the Extensor brevis pollicis below. Its lower third is broad, convex, and covered by the tendons of the muscles, which subsequently run in the grooves on the lower end of the bone.

The **external surface** is rounded and convex throughout its entire extent. Its upper third gives attachment to the Supinator brevis muscle. About its centre is seen a rough ridge, for the insertion of the Pronator radii teres muscle. Its lower part is narrow, and covered by the tendons of the Extensor ossis metacarpi pollicis and Extensor brevis pollicis muscles.

The **Lower Extremity** of the radius is large, of quadrilateral form, and provided with two articular surfaces—one at the extremity, for articulation with the carpus, and one at the inner side of the bone, for articulation with the ulna. The carpal articular surface is of triangular form, concave, smooth, and divided by a slight antero-posterior ridge into two parts. Of these, the external is of a triangular form, and articulates with the scaphoid bone; the inner, quadrilateral, articulates with the semilunar. The articular surface for the ulna is called the *sigmoid cavity* of the radius; it is narrow, concave, smooth, and articulates with the head of the ulna. The circumference of this end of the bone presents three surfaces—an anterior, external, and posterior. The *anterior surface*, rough and irregular, affords attachment to the anterior ligament of the wrist-joint. The *external surface* is prolonged obliquely downward into a strong, conical projection, the *styloid process*, which gives attachment by its base to the tendon of the Supinator longus, and by its apex to the external lateral ligament of the wrist-joint. The outer surface of this process is marked by a flat groove, which runs obliquely downward and forward, and gives passage to the tendons of the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis. The *posterior surface* is convex, affords attachment to the posterior ligament of the wrist, and is marked by three grooves. Proceeding from without inward, the first groove is broad but

shallow, and subdivided into two by a slightly elevated ridge: the outer of these two transmits the tendon of the Extensor carpi radialis longior, the inner the tendon of the Extensor carpi radialis brevior. The second, which is near the centre of the bone, is a deep but narrow groove, bounded on its outer side by a sharply-defined ridge; it is directed obliquely from above, downward and outward, and transmits the tendon of the Extensor longus pollicis. The third, lying most internally, is a broad groove, for the passage of the tendons of the Extensor indicis and Extensor communis digitorum.

Structure.—Similar to that of the other long bones.

Development (Fig. 103).—By *three* centres: one for the shaft and one for each extremity. That for the shaft makes its appearance near the centre of the bone, about the eighth week of foetal life. About the end of the second year ossification commences in the lower epiphysis, and about the fifth year in the upper end. At the age of seventeen or eighteen the upper epiphysis becomes joined to the shaft, the lower epiphysis becoming united about the twentieth year.

Articulation.—With four bones: the humerus, ulna, scaphoid, and semilunar.

Attachment of Muscles.—To nine: to the tuberosity, the Biceps; to the oblique ridge, the Supinator brevis, Flexor sublimis digitorum, and Flexor longus pollicis; to the shaft (its anterior surface), the Flexor longus pollicis and Pronator quadratus; (its posterior surface), the Extensor ossis metacarpi pollicis and Extensor brevis pollicis; (its outer surface), the Pronator radii teres; and to the styloid process, the Supinator longus.

Surface Form.—Just below and a little in front of the posterior surface of the external condyle a part of the head of the radius may be felt, covered by the orbicular and external lateral ligaments. There is in this situation a little dimple in the skin, which is most visible when the arm is extended, and which marks the position of the head of the bone. If the finger is placed on this dimple and the forearm pronated and supinated, the head of the bone will be distinctly perceived rotating in the lesser sigmoid cavity. The upper half of the shaft of the radius cannot be felt, as it is surrounded by the fleshy bellies of the muscles arising from the external condyle. The lower half of the shaft can be readily examined, though covered by tendons and muscles and not strictly subcutaneous. If traced downward, the shaft will be felt to terminate in a lozenge-shaped, convex surface on the outer side of the base of the styloid process. This is the only subcutaneous part of the bone, and from its lower extremity the apex of the styloid process will be felt bending inward toward the wrist. About the middle of the posterior aspect of the lower extremity of the bone is a well-marked ridge, best perceived when the hand is slightly flexed on the wrist. It forms the outer boundary of the oblique groove on the posterior surface of the bone, through which the tendon of the Extensor longus pollicis runs, and serves to keep that tendon in its place.

Surgical Anatomy.—The two bones of the forearm are more often broken together than is either the radius or ulna separately. It is therefore convenient to consider the fractures of these two bones together in the first instance, and subsequently to mention the principal fractures which take place in each bone individually. These fractures may be produced by either direct or indirect violence, though more commonly by direct violence. When indirect force is applied to the forearm the radius generally alone gives way, though both bones may suffer. The fracture from indirect force generally takes place somewhere about the middle of the bones; fracture from direct violence may occur at any part, more often, however, in the lower half of the bone. The fracture is usually transverse, but may be more or less oblique. A point of interest in connection with these fractures is the tendency that there is for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other, and therefore diminishes the risk of the bones becoming united across the interosseous membrane. The splints, anterior and posterior, which are

FIG. 103.—Plan of the development of the radius. By three centres.

applied in these cases should be rather wider than the limb, so as to prevent any lateral pressure on the bones. For in these cases there is a greater liability to gangrene from the pressure of the splints than in other parts of the body. This is no doubt due principally to two causes: (1) the flexion of the forearm compressing to a certain extent the brachial artery and retarding the flow of blood to the limb; and (2) the superficial position of the two main arteries of the forearm in a part of their course, and their liability to be compressed by the splints. The special fractures of the ulna are—(1) Fracture of the olecranon. This may be caused by direct violence, falls on the elbow with the forearm flexed, or by muscular action by the sudden contraction of the triceps. The most common place for the fracture to occur is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture may be either transverse or oblique; but any part may be broken, even a thin shell may be torn off. Fractures from direct violence are occasionally comminuted. The displacement is sometimes very slight, owing to the fibrous structures around the process not being torn. (2) Fracture of the coronoid process sometimes occurs as a complication of dislocation backward of the bones of the forearm, but it is doubtful if it ever occurs as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually take place at the middle of the bone or a little below it. They are almost always the result of direct violence. (4) The styloid process may be knocked off by direct violence. Fractures of the radius consist of—(1) Fracture of the head of the bone; this generally occurs in conjunction with some other lesion, but may occur as an uncomplicated injury. (2) Fracture of the neck may also take place, but is generally complicated with other injury. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. They may take place from either direct or indirect violence. In fractures of the upper third of the shaft of the bone, that is to say, above the insertion of the Pronator radii teres, the displacement is very great. The upper fragment is strongly supinated by the Biceps and Supinator brevis, and flexed by the Biceps; while the lower fragment is pronated and drawn toward the ulna by the two pronators. If such a fracture is put up in the ordinary position, midway between supination and pronation, the fracture will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movements of the hand will result. The limb should be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles's fracture). The fracture is transverse, and generally takes place about an inch from the lower extremity. It is caused by falls on the palm of the hand, and is an injury of advanced life, occurring more frequently in the female than the male. In consequence of the manner in which the fracture is caused, the upper fragment becomes driven into the lower, and impaction is the result; or else the lower fragment becomes split up into two or more pieces, so that no fixation occurs. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles's fracture may be distinguished from other injuries in this neighborhood—especially dislocation, with which it is liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural condition of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna; that is to say, nearer the ground. After fracture or separation of the epiphysis this process is on the same or higher level than that of the ulna, whereas it would be unaltered in position in dislocation.

THE HAND.

The skeleton of the **Hand** is subdivided into three segments—the **Carpus** or wrist-bones; the **Metacarpus** or bones of the palm; and the **Phalanges** or bones of the digits.

The Carpus.

The bones of the **Carpus** (*χαρπός*, the wrist), eight in number, are arranged in two rows. Those of the upper row, enumerated from the radial to the ulnar side, are the scaphoid, semilunar, cuneiform, and pisiform; those of the lower row, enumerated in the same order, are the trapezium, trapezoid, os magnum, and unciform.

Common Characters of the Carpal Bones.

Each bone (excepting the pisiform) presents six surfaces. Of these the *anterior* or *palmar* and the *posterior* or *dorsal* are rough for ligamentous attachment, the dorsal surface being the broader, except in the scaphoid and semilunar. The *superior* or *proximal* and *inferior* or *distal* are articular, the superior generally convex, the inferior concave; and the *internal* and *external* are also articular when in contact with contiguous bones, otherwise rough and tubercular. The structure in all is similar, consisting of cancellous tissue enclosed in a layer of compact bone. Each bone is also developed from a single centre of ossification.

FIG. 104.—Bones of the left hand. Dorsal surface.

Bones of the Upper Row.

SCAPHOID (Fig. 106).

FIG. 106.—The left scaphoid.

The **Scaphoid** (*σκάφη*, a boat, *εἶδος*, like) is the largest bone of the first row. It has received its name from its fancied resemblance to a boat, being broad at one end and narrowed like a prow at the opposite. It is situated at the upper and outer part of the carpus, its long axis being from above, downward, outward, and forward. The *superior surface* is convex, smooth, of triangular shape, and articulates with the lower end of the radius. The *inferior surface*, directed downward, outward, and backward, is smooth, convex, also triangular, and divided by a slight ridge into two parts, the external of which articulates with the trapezium, the inner with the trapezoid. The *posterior or dorsal surface* presents a narrow, rough groove which runs the entire length of the bone and serves for the attachment of ligaments. The *anterior or palmar surface* is concave above, and elevated at its lower and outer part into a prominent rounded tuberosity, which projects forward from the front of the carpus and gives attachment to the anterior annular ligament of the wrist and sometimes a few fibres of the Abductor pollicis. The *external surface* is rough and narrow, and gives attachment to the external lateral ligament of the wrist. The *internal surface* presents two articular facets: of these, the superior or smaller one is flattened, of semilunar form, and articulates with the semilunar; the inferior or larger is concave, forming, with the semilunar bone, a concavity for the head of the os magnum.

To ascertain to which side the bone belongs, hold it with the superior or radial convex, articular, surface upward, and the posterior surface—*i. e.*, the narrow, non-articular, grooved surface—toward you. The tubercle on the outer surface points to the side to which the bone belongs.¹

Articulations.—With five bones: the radius above, trapezium and trapezoid below, os magnum and semilunar internally.

Attachment of Muscles.—Occasionally a few fibres of the Abductor pollicis.

SEMILUNAR (Fig. 107).

FIG. 107.—The left semilunar.

The **Semilunar** (*semi*, half; *luna*, moon) bone may be distinguished by its deep concavity and crescentic outline. It is situated in the centre of the upper

¹ In these directions each bone is supposed to be placed in its natural position—that is, such a position as it would occupy when the arm is hanging by the side, the forearm in a position of supination, the thumb being directed outward, and the palm of the hand looking forward.

row of the carpus, between the scaphoid and cuneiform. The *superior surface*, convex, smooth, and bounded by four edges, articulates with the radius. The *inferior surface* is deeply concave, and of greater extent from before backward than transversely: it articulates with the head of the os magnum and by a long, narrow facet (separated by a ridge from the general surface) with the unciform bone. The *anterior* or *palmar* and *posterior* or *dorsal surfaces* are rough, for the attachment of ligaments, the former being the broader and of a somewhat rounded form. The *external surface* presents a narrow, flattened, semilunar facet for articulation with the scaphoid. The *internal surface* is marked by a smooth, quadrilateral facet, for articulation with the cuneiform.

Hold it with the convex articular surface for the radius upward, and the narrowest non-articular surface toward you. The semilunar facet for the scaphoid will be on the side to which the bone belongs.

Articulations.—With five bones: the radius above, os magnum and unciform below, scaphoid and cuneiform on either side.

CUNEIFORM (Fig. 108).

The **Cuneiform** (*cuneus*, a wedge; *forma*, likeness) may be distinguished by its pyramidal shape (*os pyramidale*), and by its having an oval, isolated facet for articulation with the pisiform bone. It is situated at the upper and inner side of the carpus. The *superior surface* presents an internal, rough, non-articular portion, and an external or articular portion, which is convex, smooth, and articulates with the triangular interarticular fibro-cartilage of the wrist. The *inferior surface*, directed outward, is concave, sinuously curved, and smooth for articulation with the unciform. The *posterior* or *dorsal surface* is rough, for the attachment of ligaments. The *anterior* or *palmar surface* presents, at its inner side, an oval facet, for articulation with the pisiform; and is rough externally, for ligamentous attachment. The *external surface*, the base of the pyramid, is marked by a flat, quadrilateral, smooth facet, for articulation with the semilunar. The *internal surface*, the summit of the pyramid, is pointed and roughened, for the attachment of the internal lateral ligament of the wrist.

Hold the bone with the surface supporting the pisiform facet away from you, and the concavo-convex surface for the unciform downward. The base of the wedge (*i. e.*, the broad end of the bone) will be on the side to which it belongs.

Articulations.—With three bones: the semilunar externally, the pisiform in front, the unciform below; and with the triangular, interarticular fibro-cartilage which separates it from the lower end of the ulna.

PISIFORM (Fig. 109).

The **Pisiform** (*pisum*, a pea; *forma*, likeness) may be known by its small size and by its presenting a single articular facet. It is situated on a plane anterior to the other bones of the carpus; it is spheroidal in form, with its long diameter directed vertically. Its *posterior surface* is a smooth, oval facet, for articulation with the cuneiform. This facet approaches the superior, but not the inferior, border of the bone. The *anterior* or *palmar surface* is rounded and rough, and gives attachment to the anterior annular ligament and to the Flexor carpi ulnaris and Abductor minimi digiti muscles. The *outer* and *inner surfaces* are also rough, the former being concave, the latter usually convex.

Hold the bone with the posterior surface—that which presents the articular facet—toward you, in such a manner that the faceted portion of the surface is uppermost. The outer, concave surface will point to the side to which it belongs.

FIG. 108.—The left cuneiform.

FIG. 109.—The left pisiform.

Articulations.—With one bone, the cuneiform.

Attachment of Muscles.—To two: the Flexor carpi ulnaris and Abductor minimi digiti; and to the anterior annular ligament.

Bones of the Lower Row.

TRAPEZIUM (Fig. 110).

The **Trapezium** (τράπεζα, a table) is of very irregular form. It may be distin-

FIG. 110.—The left trapezium.

guished by a deep groove, for the tendon of the Flexor carpi radialis muscle. It is situated at the external and inferior part of the carpus, between the scaphoid and first metacarpal bone. The *superior surface*, concave and smooth, is directed upward and inward, and articulates with the scaphoid. The *inferior surface*, directed downward and inward, is oval, concave from side to side, convex from before backward, so as to form a saddle-shaped surface, for articulation with the base of the first metacarpal bone. The *anterior or palmar surface* is narrow and rough. At its upper part is a deep groove running from above obliquely downward and inward; it transmits the tendon of the Flexor carpi radialis, and is bounded externally by a prominent ridge, the oblique ridge of the trapezium. This surface gives attachment to the Abductor pollicis, Flexor ossis metacarpi pollicis, and Flexor brevis pollicis muscles, and the anterior annular ligament. The *posterior or dorsal surface* is rough. The *external surface* is also broad and rough, for the attachment of ligaments. The *internal surface* presents two articular facets: the upper one, large and concave, articulates with the trapezoid; the lower one, small and oval, with the base of the second metacarpal bone.

Hold the bone with the saddle-shaped surface downward and the grooved surface away from you. The prominent, rough, non-articular surface points to the side to which the bone belongs.

Articulations.—With four bones: the scaphoid above, the trapezoid and second metacarpal bones internally, the first metacarpal below.

Attachment of Muscles.—Abductor pollicis, Flexor ossis metacarpi pollicis, and part of the Flexor brevis pollicis.

TRAPEZOID (Fig. 111).

The **Trapezoid** is the smallest bone in the second row. It may be known by its wedge-shaped form, the broad end of the wedge forming the dorsal, the narrow

FIG. 111.—The left trapezoid.

end the palmar, surface, and by its having four articular surfaces touching each

other and separated by sharp edges. The *superior surface*, quadrilateral in form, smooth, and slightly concave, articulates with the scaphoid. The *inferior surface* articulates with the upper end of the second metacarpal bone; it is convex from side to side, concave from before backward, and subdivided by an elevated ridge into two unequal lateral facets. The *posterior or dorsal* and *anterior or palmar surfaces* are rough, for the attachment of ligaments, the former being the larger of the two. The *external surface*, convex and smooth, articulates with the trapezium. The *internal surface* is concave and smooth in front, for articulation with the os magnum; rough behind, for the attachment of an interosseous ligament.

Hold the bone with the larger, non-articular surface toward you, and the smooth, quadrilateral articular surface upward. The convex, articular surface will point to the side to which the bone belongs.¹

Articulations.—With four bones: the scaphoid above, second metacarpal bone below, trapezium externally, os magnum internally.

OS MAGNUM (Fig. 112).

The **Os Magnum** is the largest bone of the carpus, and occupies the centre of the wrist. It presents, above, a rounded portion or head, which is received into

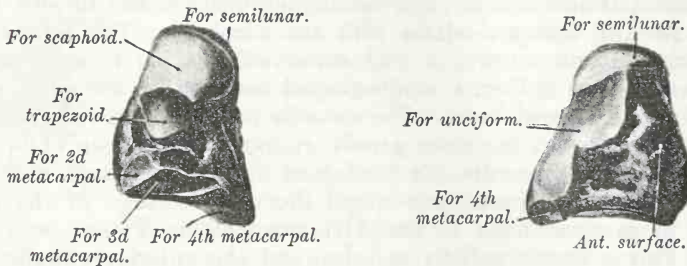

FIG. 112.—The left os magnum.

the concavity formed by the scaphoid and semilunar bones; a constricted portion or neck; and, below, the body. The *superior surface* is rounded, smooth, and articulates with the semilunar. The *inferior surface* is divided by two ridges into three facets, for articulation with the second, third, and fourth metacarpal bones, that for the third (the middle facet) being the largest of the three. The *posterior or dorsal surface* is broad and rough; the *anterior or palmar*, narrow, rounded, and also rough, for the attachment of ligaments and a part of the Adductor obliquus pollicis. The *external surface* articulates with the trapezoid by a small facet at its anterior inferior angle, behind which is a rough depression for the attachment of an interosseous ligament. Above this is a deep and rough groove, which forms part of the neck and serves for the attachment of ligaments, bounded superiorly by a smooth, convex surface, for articulation with the scaphoid. The *internal surface* articulates with the unciform by a smooth, concave, oblong facet which occupies its posterior and superior parts, and is rough in front, for the attachment of an interosseous ligament.

Hold the bone with the broader, non-articular surface toward you, and the head upward. The small, articular facet at the anterior inferior angle of the external surface will point to the side to which the bone belongs.

Articulations.—With seven bones: the scaphoid and semilunar above; the second, third, and fourth metacarpal below; the trapezoid on the radial side; and the unciform on the ulnar side.

Attachment of Muscles.—Part of the Adductor obliquus pollicis.

¹Occasionally in a badly marked bone there is some difficulty in ascertaining to which side the bone belongs; the following method will sometimes be found useful: Hold the bone with its broader, non-articular surface upward, so that its sloping border is directed toward you. The border will slope to the side to which the bone belongs.

UNCIFORM (Fig. 113).

The **Unciform** (*uncus*, a hook; *forma*, likeness) may be readily distinguished

FIG. 113.—The left unciform.

by its wedge-shaped form and the hook-like process that projects from its palmar surface. It is situated at the inner and lower angle of the carpus, with its base downward, resting on the two inner metacarpal bones, and its apex directed upward and outward. The *superior surface*, the apex of the wedge, is narrow, convex, smooth, and articulates with the semilunar. The *inferior surface* articulates with the fourth and fifth metacarpal bones, the concave surface for each being separated by a ridge which runs from before backward. The *posterior or dorsal surface* is triangular and rough, for ligamentous attachment. The *anterior or palmar surface* presents, at its lower and inner side, a curved, hook-like process of bone, the *unciform process*, directed from the palmar surface forward and outward. It gives attachment by its apex to the annular ligament and Flexor carpi ulnaris; by its inner surface to the Flexor brevis minimi digiti and the Flexor ossis metacarpi minimi digiti; and is grooved on its outer side, for the passage of the Flexor tendons into the palm of the hand. This is one of the four eminences on the front of the carpus to which the anterior annular ligament is attached, the others being the pisiform internally, the oblique ridge of the trapezium and the tuberosity of the scaphoid externally. The *internal surface* articulates with the cuneiform by an oblong facet cut obliquely from above, downward and inward. The *external surface* articulates with the os magnum by its upper and posterior part, the remaining portion being rough, for the attachment of ligaments.

Hold the bone with the hooked process away from you, and the articular surface, divided into two parts, for the metacarpal bones, downward. The concavity of the process will be on the side to which the bone belongs.

Articulations.—With five bones: the semilunar above, the fourth and fifth metacarpal below, the cuneiform internally, the os magnum externally.

Attachment of Muscles.—To three: the Flexor brevis minimi digiti, the Flexor ossis metacarpi minimi digiti, the Flexor carpi ulnaris.

The Metacarpus.

The **Metacarpal Bones** are five in number: they are long, cylindrical bones, presenting for examination a shaft and two extremities.

Common Characters of the Metacarpal Bones.

The **Shaft** is prismoid in form and curved longitudinally, so as to be convex in the longitudinal direction behind, concave in front. It presents three surfaces: two lateral and one posterior. The *lateral surfaces* are concave, for the attachment of the Interossei muscles, and separated from one another by a prominent anterior ridge. The *posterior or dorsal surface* presents in its distal half a smooth, triangular, flattened area which is covered, in the recent state, by the tendons of the Extensor muscles. This triangular surface is bounded by two lines, which commence in small tubercles situated on the dorsal aspect on either side of the

digital extremity, and, running backward, converge to meet together a little behind the centre of the bone and form a ridge which runs along the rest of the dorsal surface to the carpal extremity. This ridge separates two lateral, sloping surfaces for the attachment of the Dorsal interossei muscles.¹ To the tubercles on the digital extremities are attached the lateral ligaments of the metacarpophalangeal joints.

The **carpal extremity**, or **base**, is of a cuboidal form, and broader behind than in front; it articulates above with the carpus, and on each side with the adjoining metacarpal bones; its *dorsal* and *palmar surfaces* are rough, for the attachment of tendons and ligaments.

The **digital extremity**, or **head**, presents an oblong surface, markedly convex from before backward, less so from side to side, and flattened laterally; it articulates with the proximal phalanx; it is broader and extends farther forward on the palmar than on the dorsal aspect. It is longer in the antero-posterior than in the transverse diameter. On either side of the head is a tubercle for the attachment of the lateral ligament of the metacarpophalangeal joint. The *posterior surface*, broad and flat, supports the Extensor tendons; the *anterior surface* is grooved in the middle line for the passage of the Flexor tendons, and marked on each side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters of the Metacarpal Bones.

The **metacarpal bone of the thumb** (Fig. 114) is shorter and wider than the rest, diverges to a greater degree from the carpus, and its *palmar surface* is directed inward toward the palm. The *shaft* is flattened and broad on its dorsal aspect, and does not present the ridge which is found on the other metacarpal bones; it is concave from above downward, on its palmar surface. The *carpal extremity*, or *base*, presents a concavo-convex surface, for articulation with the trapezium; it has no lateral facets, but presents externally a tubercle for the insertion of the Extensor ossis metacarpi pollicis. The *digital extremity* is less convex than that of the other metacarpal bones, broader from side to side than from before backward. It presents on its palmar aspect two distinct articular eminences for the two sesamoid bones in the tendons of the Flexor brevis pollicis, the outer one being the larger of the two.

FIG. 114.—The first metacarpal. (Left.)

The side to which this bone belongs may be known by holding it in the position it occupies in the hand, with the carpal extremity upward and the dorsal surface backward; the tubercle for the Extensor ossis metacarpi pollicis will point to the side to which it belongs.

Attachment of Muscles.—To four: the Flexor ossis metacarpi pollicis, the Extensor ossis metacarpi pollicis, the Flexor brevis pollicis, and the First dorsal interosseous.

The **metacarpal bone of the index finger** (Fig. 115) is the longest and its base the largest of the other four. Its *carpal extremity* is prolonged upward and inward, forming a prominent ridge. The dorsal and palmar surfaces of this extremity are rough, for the attachment of tendons and ligaments. It presents four articular facets: three on the upper aspect of the base: the middle one of the three is the largest, concave from side to side, convex from before backward, for articulation with the trapezoid; the external one is a small, flat, oval facet, for articulation with the trapezium; the internal one on the summit of the ridge is

¹ By these sloping surfaces the metacarpal bones of the hand may be at once differentiated from the metatarsal bone of the foot.

long and narrow, for articulation with the os magnum. The fourth facet is on the inner or ulnar side of the extremity of the bone, and is for articulation with the third metacarpal bone.

The side to which this bone belongs is indicated by the absence of the lateral facet on the outer (radial) side of its base, so that if the bone is placed with its base toward the student and the palmar surface upward, the side on which there is no lateral facet will be that to which it belongs.

Attachment of Muscles.—To six: Flexor carpi radialis, Extensor carpi radialis longior, Adductor obliquus pollicis, First and Second dorsal interosseous, and First palmar interosseous.

The metacarpal bone of the middle finger (Fig. 116) is a little smaller than the preceding: it presents a pyramidal eminence (the styloid process) on the radial side of its base (dorsal aspect) which extends upward behind the os magnum; immediately below this, on the dorsal aspect, is a rough surface for the attachment of

FIG. 115.—The second metacarpal. (Left.)

FIG. 116.—The third metacarpal. (Left.)

the Extensor carpi radialis brevior. The carpal, articular facet is concave behind, flat in front, and articulates with the os magnum. On the radial side is a smooth, concave facet, for articulation with the second metacarpal bone, and on the ulnar side two small, oval facets, for articulation with the fourth metacarpal.

The side to which this bone belongs is easily recognized by the styloid process on the radial side of its base. With the palmar surface uppermost and the base toward the student, this process points toward the side to which the bone belongs.

Attachment of Muscles.—To six: Extensor carpi radialis brevior, Flexor carpi radialis, Adductor transversus pollicis, Adductor obliquus pollicis, and Second and Third dorsal interosseous.

The metacarpal bone of the ring finger (Fig. 117) is shorter and smaller than the preceding, and its base small and quadrilateral; the carpal surface of the base presenting two facets, a large one externally, for articulation with the unciform, and a small one internally, for the os magnum. On the radial side are two oval facets, for articulation with the third metacarpal bone; and on the ulnar side a single concave facet, for the fifth metacarpal.

If this bone is placed with the base toward the student and the palmar surface

upward, the radial side of the base, which has two facets for articulation with the third metacarpal bone, will be on the side to which it belongs. If, as sometimes happens in badly marked bones, one of these facets is indistinguishable, the side may be known by selecting the surface on which the larger articular facet is present. This facet is for the fifth metacarpal bone, and would therefore be situated on the ulnar side—that is, the one to which the bone does *not* belong.

Attachment of Muscles.—To three: the Third and Fourth dorsal and Second palmar interosseous.

The **metacarpal bone of the little finger** (Fig. 118) presents on its base one facet, which is concavo-convex, and which articulates with the unciform bone, and one

FIG. 117.—The fourth metacarpal. (Left.)

FIG. 118.—The fifth metacarpal. (Left.)

lateral, articular facet, which articulates with the fourth metacarpal bone. On its ulnar side is a prominent tubercle, for the insertion of the tendon of the Extensor carpi ulnaris. The dorsal surface of the shaft is marked by an oblique ridge which extends from near the ulnar side of the upper extremity to the radial side of the lower. The outer division of this surface serves for the attachment of the Fourth dorsal interosseous muscle; the inner division is smooth and covered by the Extensor tendons of the little finger.

If this bone is placed with its base toward the student and its palmar surface upward, the side of the head which has a lateral facet will be that to which the bone belongs.

Attachment of Muscles.—To five: the Extensor carpi ulnaris, Flexor carpi ulnaris, Flexor ossis metacarpi minimi digiti, Fourth dorsal, and Third palmar interosseous.

Articulations.—Besides the phalangeal articulations, the first metacarpal bone articulates with the trapezium; the second with the trapezium, trapezoid, os magnum, and third metacarpal bones; the third with the os magnum and second and fourth metacarpal bones; the fourth with the os magnum, unciform, and third and fifth metacarpal bones; and the fifth with the unciform and fourth metacarpal.

The *first* has no lateral facets on its carpal extremity; the *second* has no lateral facet on its radial side, but one on its ulnar side; the third has one on its radial and two on its ulnar side; the fourth has two on its radial and one on its ulnar side; and the fifth has only one on its radial side.

The Phalanges.

The **Phalanges** (*internodia*) are the bones of the fingers; they are fourteen in number, three for each finger, and two for the thumb. They are long bones, and present for examination a shaft and two extremities. The *shaft* tapers from above downward, is convex posteriorly, concave in front from above downward, flat from side to side, and marked laterally by rough ridges, which give attachment to the fibrous sheaths of the Flexor tendons. The *metacarpal extremity*, or *base*, in the first row presents an oval, concave, articular surface, broader from side to side than from before backward; and the same extremity in the other two rows, a double concavity, separated by a longitudinal median ridge, extending from before backward. The *digital extremities* are smaller than the bases, and terminate, in the first and second rows, in two small, lateral condyles, separated by a slight groove; the articular surface being prolonged farther forward on the palmar than on the dorsal surface, especially in the first row.

The **Ungual Phalanges** are convex on their dorsal, flat on their palmar, surfaces; they are recognized by their small size and by a roughened, elevated surface of a horseshoe form on the palmar aspect of their ungual extremity, which serves to support the sensitive pulp of the finger.

Articulations.—The first row, with the metacarpal bones and the second row of phalanges; the second row, with the first and third; the third, with the second row.

Attachment of Muscles.—To the base of the first phalanx of the thumb, five muscles: the Extensor brevis pollicis, Flexor brevis pollicis, Abductor pollicis, Adductor transversus and obliquus pollicis. To the second phalanx, two: the Flexor longus pollicis and the Extensor longus pollicis. To the base of the first phalanx of the index finger, the First dorsal and the First palmar interosseous; to that of the middle finger, the Second and Third dorsal interosseous; to that of the ring finger, the Fourth dorsal and the Second palmar interosseous; and to that of the little finger, the Third palmar interosseous, the Flexor brevis minimi digiti, and Abductor minimi digiti. To the second phalanges, the Flexor sublimis digitorum, Extensor communis digitorum, and, in addition, the Extensor indicis to the index finger, the Extensor minimi digiti to the little finger. To the third phalanges, the Flexor profundus digitorum and Extensor communis digitorum.

Surface Form.—On the front of the wrist are two subcutaneous eminences, one on the radial side, the larger and flatter, due to the tuberosity of the scaphoid and the ridge on the trapezium; the other, on the ulnar side, caused by the pisiform bone. The tubercle of the scaphoid is to be felt just below and in front of the apex of the styloid process of the radius. It is best perceived by extending the hand on the forearm. Immediately below is to be felt another prominence, better marked than the tubercle; this is the ridge on the trapezium which gives attachment to some of the short muscles of the thumb. On the inner side of the front of the wrist the pisiform bone is to be felt, forming a small but prominent projection in this situation. It is some distance below the styloid process of the ulna, and may be said to be just below the level of the styloid process of the radius. The rest of the front of the carpus is covered by tendons and the annular ligament, and entirely concealed, with the exception of the hooked process of the ulnar, which can only be made out with difficulty. The back of the carpus is convex and covered by the Extensor tendons, so that none of the posterior surfaces of the bones are to be felt, with the exception of the cuneiform on the inner side. Below the carpus the dorsal surfaces of the metacarpal bones, except the fifth, are covered by tendons, and are scarcely visible except in very thin hands. The dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length, and is plainly to be perceived and felt. In addition to this, slightly external to the middle line of the hand, is a prominence, frequently well marked, but occasionally indistinct, formed by the base of the metacarpal of the middle finger. The heads of the metacarpal bones are plainly to be felt and seen, rounded in contour and standing out in bold relief under the skin, when the fist is clenched. It should be borne in mind that when the fingers are flexed on the hand, the articular surfaces of the first phalanges glide off the heads of the metacarpal bones on to their anterior surfaces, so that the heads of these bones form the prominence of the knuckles and receive the force of any blow which may be given. The head of the third metacarpal bone is the most prominent, and receives the greater part of the shock of the blow. This bone articulates with the os magnum, so that the concussion is carried through this bone to the scaphoid and semilunar, with which the head of the os magnum articulates, and by these bones is transferred to the radius, along which it may be carried to the capitellum of the humerus. The enlarged extremities of the phalanges are to be plainly felt: they form the

joints of the fingers. When the digits are bent the proximal phalanges of the joints form prominences, which in the joint between the first and second phalanges is slightly hollowed, in accordance with the grooved shape of their articular surfaces, whilst at the last row the prominence is flattened and square-shaped. In the palm of the hand the four inner metacarpal bones are covered by muscles, tendons, and the palmar fascia, and no part of them but their heads is to be distinguished. With regard to the thumb, on the dorsal aspect the base of the metacarpal bone forms a prominence below the styloid process of the radius; the shaft is to be felt, covered by tendons, terminating at its head in a flattened prominence, in front of which can be felt the sesamoid bones.

Surgical Anatomy.—The carpal bones are little liable to fracture, except from extreme violence, when the parts are so comminuted as to necessitate amputation. Occasionally they are the seat of tubercular disease. The metacarpal bone and the phalanges are not unfrequently broken from direct violence. The first metacarpal bone is the one most commonly fractured; then the second, the fourth, and the fifth, the third being the one least frequently broken. There are two diseases of the metacarpal bones and phalanges which require special mention on account of the frequency of their occurrence. One is tubercular dactylitis, consisting in a deposit of tubercular material in the medullary canal, expanding the bone, with subsequent caseation and resulting necrosis. The other is chondroma, which is perhaps more frequently found in connection with the metacarpal bones and phalanges than with any other bones. They are commonly multiple, and may spring either from the medullary canal or from the periosteum.

Development of the Bones of the Hand.

The **Carpal Bones** are each developed by a *single* centre. At birth they are all cartilaginous. Ossification proceeds in the following order (Fig. 119): In the

FIG. 119.—Plan of the development of the hand.

os magnum and unciform an ossific point appears during the first year, the former preceding the latter; in the cuneiform, at the third year; in the trapezium and semilunar, at the fifth year, the former preceding the latter; in the scaphoid, at

the sixth year; in the trapezoid, during the eighth year; and in the pisiform, about the twelfth year.

Occasionally an additional bone, the *os centrale*, is found in the carpus, lying between the scaphoid, trapezoid, and *os magnum*. During the second month of foetal life it is represented by a small cartilaginous nodule, which, however, fuses with the cartilaginous scaphoid about the third month. Sometimes the styloid process of the third metacarpal is detached and forms an additional ossicle.

The **Metacarpal Bones** are each developed by *two* centres: one for the shaft and one for the digital extremity for the four inner metacarpal bones; one for the shaft and one for the base for the metacarpal bone of the thumb, which in this respect resembles the phalanges.¹ Ossification commences in the centre of the shaft about the eighth or ninth week, and gradually proceeds to either end of the bone: about the third year the digital extremities of the four inner metacarpal bones and the base of the first metacarpal begin to ossify, and they unite about the twentieth year.

The **Phalanges** are each developed by *two* centres: one for the shaft and one for the base. Ossification commences in the shaft, in all three rows, at about the eighth week, and gradually involves the whole of the bone excepting the upper extremity. Ossification of the base commences in the first row between the third and fourth years, and a year later in those of the second and third rows. The two centres become united, in each row, between the eighteenth and twentieth years.

In the ungual phalanges the centre for the shaft appears at the distal extremity of the phalanx, instead of at the middle of the shaft, as is the case with the other phalanges.

THE LOWER EXTREMITY.

The bones of the lower extremity consist of those of the pelvic girdle, of the thigh, of the leg, and of the foot.

The Pelvic Girdle.

The **Pelvic Girdle** consists of a single bone, the *os innominatum*, by which the thigh is connected to the trunk.

The Os Innominatum.

The **Os Innominatum** (*in*, not; *nomino*, I name), or *nameless bone*, so called from bearing no resemblance to any known object, is a large, irregularly shaped, flat bone, constricted in the centre and expanded above and below. With its fellow of the opposite side it forms the sides and anterior wall of the pelvic cavity. In young subjects it consists of three separate parts, which meet and form the large, cup-like cavity, the *acetabulum*, situated near the middle of the outer surface of the bone; and, although in the adult these have become united, it is usual to describe the bone as divisible into three portions—the ilium, the ischium, and the os pubis.

The **ilium**, so called from its supporting the flank (*ilia*), is the superior, broad, and expanded portion which runs upward from the acetabulum and forms the prominence of the hip.

The **ischium** (*ισχίον*, the hip) is the inferior and strongest portion of the bone; it proceeds downward from the acetabulum, expands into a large tuberosity, and then, curving forward, forms, with the descending ramus of the os pubis, a large aperture, the obturator foramen.

The **os pubis** is that portion which extends inward and downward from the acetabulum to articulate in the middle line with the bone of the opposite side: it

¹ Allan Thomson has demonstrated the fact that the first metacarpal bone is often developed from three centres; that is to say, there is a separate nucleus for the distal end, forming a distinct epiphysis, visible at the age of seven or eight years. He also states that there are traces of a proximal epiphysis in the second metacarpal bone.—*Journal of Anatomy*, 1869.

it terminates, it becomes less marked, and is often altogether lost. Behind this line is a narrow semilunar surface, the upper part of which is rough and affords attachment to part of the *Gluteus maximus*; the lower part is smooth and has no muscular fibres attached to it. The *middle curved line*, the longest of the three, commences at the crest, about an inch behind its anterior extremity, and, taking a curved direction downward and backward, terminates at the upper part of the great sacro-sciatic notch. The space between the superior and middle curved lines and

FIG. 121.—Right os innominatum. Internal surface.

the crest is concave, and affords attachment to the *Gluteus medius* muscle. Near the central part of this line may often be observed the orifice of a nutrient foramen. The *inferior curved line*, the least distinct of the three, commences in front at the notch on the anterior border, and, taking a curved direction backward and downward, terminates at the middle of the great sacro-sciatic notch. The surface of bone included between the middle and inferior curved lines is concave from above downward, convex from before backward, and affords attachment to the *Gluteus minimus* muscle. Beneath the inferior curved line, and corresponding to the upper

part of the acetabulum, is a roughened surface (sometimes a depression), to which is attached the reflected tendon of the Rectus femoris muscle.

The **Internal Surface** (Fig. 121) of the ilium is bounded above by the crest; below it is continuous with the pelvic surface of the os pubis and ischium, a faint line only indicating the place of union; and before and behind it is bounded by the anterior and posterior borders. It presents a large, smooth, concave surface, called the *iliac fossa*, or *venter ilii*, which lodges the Iliacus muscle, and presents at its lower part the orifice of a nutrient canal; and below this a smooth, rounded border (the *linea ilio-pectinea*), which separates the iliac fossa from that portion of the internal surface which enters into the formation of the true pelvis, and which gives attachment to part of the Obturator internus muscle. Behind the iliac fossa is a rough surface divided into two portions, an anterior and a posterior. The anterior or auricular surface, so called from its resemblance in shape to the ear, is coated with cartilage in the recent state, and articulates with a surface of similar shape on the side of the sacrum. The posterior portion is rough, for the attachment of the posterior sacro-iliac ligaments and for a part of the origin of the Erector and Multifidus spinæ.

The **crest** of the ilium is convex in its general outline and sinuously curved, being concave inward in front, concave outward behind. It is longer in the female than in the male, very thick behind, and thinner at the centre than at the extremities. It terminates at either end in a prominent eminence, the *anterior superior* and *posterior superior spinous process*. The surface of the crest is broad, and divided into an external lip, an internal lip, and an intermediate space. About two inches behind the anterior superior spinous process there is a prominent tubercle on the outer lip. To the external lip is attached the Tensor fasciæ femoris, Obliquus externus abdominis, and Latissimus dorsi, and along its whole length, the fascia lata; to the space between the lips, the Internal oblique; to the internal lip, the Transversalis, Quadratus lumborum, and Erector spinæ, the Iliacus, and the fascia iliaca.

The **anterior border** of the ilium is concave. It presents two projections, separated by a notch. Of these, the uppermost, situated at the junction of the crest and anterior border, is called the *anterior superior spinous process* of the ilium, the outer border of which gives attachment to the fascia lata and the origin of the Tensor fasciæ femoris; its inner border, to the Iliacus; while its extremity affords attachment to Poupart's ligament and the origin of the Sartorius. Beneath this eminence is a notch which gives attachment to the Sartorius muscle, and across which passes the external cutaneous nerve. Below the notch is the *anterior inferior spinous process*, which terminates in the upper lip of the acetabulum; it gives attachment to the straight tendon of the Rectus femoris muscle and the ilio-femoral ligament. On the inner side of the anterior inferior spinous process is a broad, shallow groove, over which passes the Ilio-psoas muscle. This groove is bounded internally by an eminence, the *ilio-pectineal*, which marks the point of union of the ilium and os pubis.

The **posterior border** of the ilium, shorter than the anterior, also presents two projections separated by a notch, the *posterior superior* and the *posterior inferior spinous processes*. The former corresponds with that portion of the inner surface of the ilium which serves for the attachment of the oblique portion of the sacro-iliac ligaments and the Multifidus spinæ; the latter, to the auricular portion which articulates with the sacrum. Below the posterior inferior spinous process is a deep notch, the *great sacro-sciatic*.

The **Ischium** forms the lower and back part of the os innominatum. It is divisible into a thick and solid portion—the *body*; a large, rough eminence, on which the trunk rests in sitting—the *tuberosity*; and a thin part which passes forward and slightly upward—the *ramus*.

The **body**, somewhat triangular in form, presents three surfaces, external, internal, and posterior; and three borders, external, internal, and posterior. The *external surface* corresponds to that portion of the acetabulum formed by the

ischium; it is smooth and concave, and forms a little more than two-fifths of the acetabular cavity; its outer margin is bounded by a prominent rim or lip, the external border, to which the cotyloid fibro-cartilage is attached. Below the acetabulum, between it and the tuberosity, is a deep groove, along which the tendon of the Obturator externus muscle runs as it passes outward to be inserted into the digital fossa of the femur. The *internal surface* is smooth, concave, and enters into the formation of the lateral boundary of the true pelvic cavity. This surface is perforated by two or three large, vascular foramina, and affords attachment to part of the Obturator internus muscle. The *posterior surface* is quadrilateral in form, broad and smooth. Below, where it joins the tuberosity, it presents a groove continuous with that on the external surface, for the tendon of the Obturator externus muscle. The lower edge of this groove is formed by the tuberosity of the ischium, and affords attachment to the Gemellus inferior muscle. This surface is limited, externally, by the margin of the acetabulum; behind, by the posterior border; it supports the Piriformis, the two Gemelli, and the Obturator internus muscles in their passage outward to the great trochanter. The *external border* forms the prominent rim of the acetabulum, and separates the posterior from the external surface. To it is attached the cotyloid fibro-cartilage. The *internal border* is thin, and forms the outer circumference of the obturator foramen. The *posterior border* of the body of the ischium presents, a little below the centre, a thin and pointed, triangular eminence, the *spine of the ischium*, more or less elongated in different subjects; its external surface gives attachment to the Gemellus superior, its internal surface to the Coccygeus and Levator ani; whilst to the pointed extremity is connected the lesser sacro-sciatic ligament. Above the spine is a notch of a large size, the *great sacro-sciatic*, converted into a foramen by the lesser sacro-sciatic ligament; it transmits the Piriformis muscle, the gluteal vessels, and superior and inferior gluteal nerves; the sciatic vessels, the greater and lesser sciatic nerves, the internal pudic vessels and nerve, and the nerves to the Obturator internus and Quadratus femoris. Of these, the gluteal vessels and superior gluteal nerve pass out above the Piriformis muscle, the other structures, below it. Below the spine is a smaller notch, the *lesser sacro-sciatic*; it is smooth, coated in the recent state with cartilage, the surface of which presents two or three ridges corresponding to the subdivisions of the tendon of the Obturator internus, which winds over it. It is converted into a foramen by the sacro-sciatic ligaments, and transmits the tendon of the Obturator internus, the nerve which supplies that muscle, and the internal pudic vessels and nerve.

The *tuberosity* presents for examination three surfaces: external, internal, and posterior. The *external surface* is quadrilateral in shape, and rough for the attachment of muscles. It is bounded above by the groove for the tendon of the Obturator externus; in front it is limited by the posterior margin of the obturator foramen, and below it is continuous with the ramus of the bone; behind, it is bounded by a prominent margin which separates it from the posterior surface. In front of this margin the surface gives attachment to the Quadratus femoris, and anterior to this to some of the fibres of origin of the Obturator externus. The lower part of the surface gives origin to part of the Adductor magnus. The *internal surface* forms part of the bony wall of the true pelvis. In front it is limited by the posterior margin of the obturator foramen. Behind, it is bounded by a sharp ridge, for the attachment of a falciform prolongation of the great sacro-sciatic ligament; it sometimes presents a groove on the inner side of this ridge for the lodgement of the internal pudic vessels and nerve; and, more anteriorly, has attached the Transversus perinæi and Erector penis muscles. The *posterior surface* is divided into two portions—a lower rough, somewhat triangular part, and an upper smooth, quadrilateral portion. The anterior portion is subdivided by a prominent vertical ridge, passing from base to apex, into two parts: the outer one gives attachment to the Adductor magnus; the inner to the great sacro-sciatic ligament. The upper portion is subdivided into two facets by an oblique ridge which runs downward and outward; from the upper and outer facet arises

the Semimembranosus; from the lower and inner, the Biceps and Semiten-dinosus.

The **ramus** is the thin, flattened part of the ischium which ascends from the tuberosity upward and inward, and joins the descending ramus of the os pubis, their point of junction being indicated in the adult by a rough line. The outer surface of the ramus is rough, for the attachment of the Obturator externus muscle, and also some fibres of the Adductor magnus; its inner surface forms part of the anterior wall of the pelvis. Its inner border is thick, rough, slightly everted, forms part of the outlet of the pelvis, and presents two ridges and an intervening space. The ridges are continuous with similar ones on the descending ramus of the os pubis: to the outer one is attached the deep layer of the superficial perineal fascia, and to the inner, the superficial layer of the triangular ligament of the urethra. If these two ridges are traced downward, they will be found to join with each other just behind the point of origin of the Transversus perinæi muscle; here the two layers of fascia are continuous behind the posterior border of the muscle. To the intervening space, just in front of the point of junction of the ridges, is attached the Transversus perinæi muscle, and in front of this a portion of the crus penis vel clitoridis and the Erector penis vel clitoridis muscle. Its outer border is thin and sharp, and forms part of the inner margin of the obturator foramen.

The **Os Pubis** forms the anterior part of the os innominatum, and, with the bone of the opposite side, forms the front boundary of the true pelvic cavity. It is divisible into a body, an ascending and a descending ramus.

The **body** is somewhat quadrilateral in shape, and presents for examination two surfaces and three borders. The *anterior surface* is rough, directed downward and outward, and serves for the attachment of various muscles. To the upper and inner angle, immediately below the crest, is attached the Adductor longus; lower down, from without inward, are attached the Obturator externus, the Adductor brevis, and the upper part of the Gracilis. The *posterior surface*, convex from above downward, concave from side to side, is smooth, and forms part of the anterior wall of the pelvis. It gives attachment to the Levator ani, Obturator internus, a few muscular fibres prolonged from the bladder, and the pubo-prostatic ligaments. The *upper border* presents for examination a prominent tubercle, which projects forward and is called the *spine*; to it are attached the outer pillar of the external abdominal ring and Poupart's ligament. Passing upward and outward from this is a prominent ridge, forming part of the *ilio-pectineal line*, which marks the brim of the true pelvis: to it are attached a portion of the conjoined tendon of the Internal oblique and Transversalis muscles, Gimbernat's ligament, and the triangular fascia of the abdomen. Internal to the spine of the os pubis is the *crest*, which extends from this process to the inner extremity of the bone. It affords attachment, anteriorly, to the conjoined tendon of the Internal oblique and Transversalis; and posteriorly, to the Rectus and Pyramidalis muscles. The point of junction of the crest with the inner border of the bone is called the *angle*; to it, as well as to the symphysis, is attached the internal pillar of the external abdominal ring. The *internal border* is articular; it is oval, covered by eight or nine transverse ridges, or a series of nipple-like processes arranged in rows, separated by grooves; they serve for the attachment of a thin layer of cartilage, placed between it and the central fibro-cartilage. The *outer border* presents a sharp margin, which forms part of the circumference of the obturator foramen and affords attachment to the obturator membrane.

The **ascending or superior ramus** extends from the body to the point of junction of the os pubis with the ilium, and forms the upper part of the circumference of the obturator foramen. It presents for examination a superior, inferior, and posterior surface, and an outer extremity. The *superior surface* presents a continuation of the ilio-pectineal line, already mentioned as commencing at the pubic spine. In front of this ridge the surface of bone is triangular in form, wider externally than internally, smooth, and is covered by the Pectineus muscle.

The surface is bounded externally by a rough eminence, the *ilio-pectineal*, which serves to indicate the point of junction of the ilium and os pubis, and gives attachment to the *Psoas parvus*, when this muscle is present. The triangular surface is bounded below by a prominent ridge, the *obturator crest*, which extends from the cotyloid notch to the spine of the os pubis. The *inferior surface* forms the upper boundary of the obturator foramen, and presents externally a broad and deep oblique groove, for the passage of the obturator vessels and nerve; and internally a sharp margin which forms part of the circumference of the obturator foramen, and to which the obturator membrane is attached. The *posterior surface* forms part of the anterior boundary of the true pelvis. It is smooth, convex from above downward, and affords attachment to some fibres of the *Obturator internus*. The *outer extremity*, the thickest part of the ramus, forms one-fifth of the cavity of the acetabulum.

The *descending* or *inferior ramus* of the os pubis is thin and flattened. It passes outward and downward, becoming narrower as it descends, and joins with the ramus of the ischium. Its *anterior surface* is rough, for the attachment of muscles—the *Gracilis* along its inner border; a portion of the *Obturator externus* where it enters into the formation of the foramen of that name; and between these two muscles the *Adductores brevis* and *magnus* from within outward. The *posterior surface* is smooth, and gives attachment to the *Obturator internus*, and, close to the inner margin, to the *Compressor urethræ*. The *inner border* is thick, rough, and everted, especially in females. It presents two ridges, separated by an intervening space. The ridges extend downward, and are continuous with similar ridges on the ascending ramus of the ischium; to the external one is attached the deep layer of the superficial perineal fascia, and to the internal one the superficial layer of the triangular ligament of the urethra. The *outer border* is thin and sharp, forms part of the circumference of the obturator foramen, and gives attachment to the obturator membrane.

The *cotyloid cavity*, or *acetabulum*, is a deep, cup-shaped, hemispherical depression, directed downward, outward, and forward; formed internally by the os pubis, above by the ilium, behind and below by the ischium, a little less than two-fifths being formed by the ilium, a little more than two-fifths by the ischium, and the remaining fifth by the pubic bone. It is bounded by a prominent, uneven rim, which is thick and strong above, and serves for the attachment of the *cotyloid ligament*, which contracts its orifice and deepens the surface for articulation. It presents below a deep notch, the *cotyloid notch*, which is continuous with a circular depression, the *fossa acetabuli*, at the bottom of the cavity: this depression is perforated by numerous apertures, lodges a mass of fat, and its margins, as well as those of the notch, serve for the attachment of the *ligamentum teres*. The notch is converted, in the natural state, into a foramen by a dense ligamentous band which passes across it. Through this foramen the nutrient vessels and nerves enter the joint.

The *obturator* or *thyroid foramen* is a large aperture situated between the ischium and os pubis. In the male it is large, of an oval form, its longest diameter being obliquely from before backward; in the female it is smaller and more triangular. It is bounded by a thin, uneven margin, to which a strong membrane is attached, and presents, anteriorly, a deep groove which runs from the pelvis obliquely inward and downward. This groove is converted into a foramen by the obturator membrane, and transmits the obturator vessels and nerve.

Structure.—This bone consists of much cancellous tissue, especially where it is thick, enclosed between two layers of dense, compact tissue. In the thinner parts of the bone, as at the bottom of the acetabulum and centre of the iliac fossa, it is usually semitransparent, and composed entirely of compact tissue.

Development (Fig. 122).—By *eight* centres: three primary—one for the ilium, one for the ischium, and one for the os pubis; and *five* secondary—one for the crest of the ilium, one for the anterior inferior spinous process (said to occur more

frequently in the male than the female), one for the tuberosity of the ischium, one for the symphysis pubis (more frequent in the female than the male), and one or more for the Y-shaped piece at the bottom of the acetabulum. These various centres appear in the following order: First, in the ilium, at the lower part of the bone, immediately above the sciatic notch, at about the eighth or ninth week; secondly, in the body of the ischium, at about the third month of fetal life; thirdly, in the body of the os pubis, between the fourth and fifth months. At birth the three primary centres are quite separate, the crest, the bottom of the acetabulum, the ischial tuberosity, and the rami of the ischium and pubes being still cartilaginous. At about the seventh or eighth year the rami of the os pubis and ischium are almost completely united by bone. About the thirteenth or fourteenth year the three divisions of the bone have extended their growth into the bottom of the acetabulum, being separated from each other by a Y-shaped portion of cartilage, which now presents traces of ossification, often by two or more centres. One of these, the *os acetabuli*, appears about the age of twelve, between the ilium and os pubis, and fuses with them about the age of eighteen. It forms the pubic part of the acetabulum. The ilium and ischium then become joined, and lastly the os pubis to the ischium, through the intervention of this Y-shaped portion. At about the age of puberty ossification takes place in each of the remaining portions, and they become joined to the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic and ischial spines.

Articulations.—With its fellow of the opposite side, the sacrum, and femur.

By eight centres { Three primary (*Ilium*, *Ischium*, and *Os Pubis*).
Five Secondary.

The three primary centres unite through Y-shaped piece about puberty.
Epiphyses appear about puberty, and unite about 25th year.

FIG. 122.—Plan of the development of the os innominatum.

Attachment of Muscles.—To the *ilium*, sixteen. To the outer lip of the crest, the Tensor vaginæ femoris, Obliquus externus abdominis, and Latissimus dorsi; to the internal lip, the Iliacus, Transversalis, Quadratus lumborum, and Erector spinæ; to the interspace between the lips, the Obliquus internus. To the outer surface of the ilium, the Gluteus maximus, Gluteus medius, Gluteus minimus, reflected tendon of the Rectus; to the upper part of the great sacro-sciatic notch, a portion of the Piriformis; to the internal surface, the Iliacus; to that portion of

the internal surface below the linea ilio-pectinea, the Obturator internus to the internal surface of the posterior superior spine, and the Multifidus spinæ; to the anterior border, the Sartorius and straight tendon of the Rectus. To the *ischium*, thirteen. To the outer surface of the ramus, the Obturator externus and Adductor magnus; to the internal surface, the Obturator internus and Erector penis. To the spine, the Gemellus superior, Levator ani, and Coccygeus. To the tuberosity, the Biceps, Semitendinosus, Semimembranosus, Quadratus femoris, Adductor magnus, Gemellus inferior, Transversus perinæi, Erector penis. To the *os pubis*, sixteen: Obliquus externus, Obliquus internus, Transversalis, Rectus, Pyramidalis, Psoas parvus, Pectineus, Adductor magnus, Adductor longus, Adductor brevis, Gracilis, Obturator externus and internus, Levator ani, Compressor urethræ, and occasionally a few fibres of the Accelerator urinæ.

The Pelvis (Figs. 123, 124).

The **Pelvis**, so called from its resemblance to a basin (*L. pelvis*), is stronger and more massively constructed than either the cranial or thoracic cavity; it is a bony ring, interposed between the lower end of the spine, which it supports, and the lower extremities, upon which it rests. It is composed of four bones: the two ossa innominata, which bound it on either side and in front, and the sacrum and coccyx, which complete it behind.

The pelvis is divided by an oblique plane passing through the prominence of the sacrum, the linea ilio-pectinea, and the upper margin of the symphysis pubis into the false and true pelvis.

The **false pelvis** is the expanded portion of the pelvic cavity which is situated above this plane. It is bounded on each side by the ossa ilii; in front it is

FIG. 123.—Male pelvis (adult).

incomplete, presenting a wide interval between the spinous processes of the ilia on either side, which is filled up in the recent state by the parietes of the abdomen; behind, in the middle line, is a deep notch. This broad, shallow cavity is fitted to support the intestines and to transmit part of their weight to the anterior wall of the abdomen, and is, in fact, really a portion of the abdominal cavity. The term false pelvis is incorrect, and this space ought more properly to be regarded as part of the hypogastric and iliac regions of the abdomen.

The **true pelvis** is that part of the pelvic cavity which is situated beneath the

plane. It is smaller than the false pelvis, but its walls are more perfect. For convenience of description it is divided into a superior circumference or inlet, an inferior circumference or outlet, and a cavity.

The **superior circumference** forms the brim of the pelvis, the included space being called the *inlet*. It is formed by the linea ilio-pectinea, completed in front

FIG. 124.—Female pelvis (adult).

by the crests of the pubic bones, and behind by the anterior margin of the base of the sacrum and sacro-vertebral angle. The *inlet* of the pelvis is somewhat heart-shaped, obtusely pointed in front, diverging on either side, and encroached upon behind by the projection forward of the promontory of the sacrum. It has three principal diameters: antero-posterior (sacro-pubic), transverse, and oblique. The antero-posterior extends from the sacro-vertebral angle to the symphysis pubis; its average measurement is four inches in the male, four and three-quarters in the female. The transverse extends across the greatest width of the inlet, from the middle of the brim on one side to the same point on the opposite; its average measurement is four and a half in the male, five and a quarter in the female. The oblique extends from the margin of the pelvis, corresponding to the ilio-pectineal eminence on one side, to the sacro-iliac articulation on the opposite side; its average measurement is four and a quarter in the male and five in the female.

The **cavity** of the true pelvis is bounded in front by the symphysis pubis; behind, by the concavity of the sacrum and coccyx, which, curving forward above and below, contracts the inlet and outlet of the canal; and laterally it is bounded by a broad, smooth, quadrangular surface of bone, corresponding to the inner surface of the body of the ischium and that part of the ilium which is below the ilio-pectineal line. The cavity is shallow in front, measuring at the symphysis an inch and a half in depth, three inches and a half in the middle, and four inches and a half posteriorly. From this description it will be seen that the cavity of the pelvis is a short, curved canal, considerably deeper on its posterior than on its anterior wall. This cavity contains, in the recent subject, the rectum, bladder, and part of the organs of generation. The rectum is placed at the back of the pelvis, and corresponds to the curve of the sacro-coccygeal column; the bladder in front, behind the symphysis pubis. In the female the uterus and vagina occupy the interval between these viscera.

The **lower circumference** of the pelvis is very irregular, and forms what is called the *outlet*. It is bounded by three prominent eminences: one posterior, formed by the point of the coccyx; and one on each side, the tuberosities of the

ischia. These eminences are separated by three notches; one in front, the *pubic arch*, formed by the convergence of the rami of the ischia and pubic bones on each side. The other notches, one on each side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above; they are called the *sacro-sciatic notches*; in the natural state they are converted into foramina by the lesser and greater sacro-sciatic ligaments. In the recent state, when the ligaments are *in situ*, the outlet of the pelvis is lozenge-shaped, bounded in front by the subpubic ligament and the rami of the os pubis and ischium; on each side by the tuberosities of the ischia; and behind by the great sacro-sciatic ligaments and the tip of the coccyx.

The diameters of the outlet of the pelvis are two, antero-posterior and transverse. The *antero-posterior* extends from the tip of the coccyx to the lower part of the symphysis pubis; its average measurement is three and a quarter inches in the male and five in the female. The antero-posterior diameter varies with the length of the coccyx, and is capable of increase or diminution on account of the mobility of that bone. The *transverse* extends from the posterior part of one ischiatic tuberosity to the same point on the opposite side: the average measurement is three and a half inches in the male and four and three-quarters in the female.¹

Position of the Pelvis.—In the erect posture the pelvis is placed obliquely with regard to the trunk of the body: the bony ring, which forms the brim of the true pelvis, is placed so as to form an angle of about 60° to 65° with the ground on which we stand. The pelvic surface of the symphysis pubis looks upward and backward, the concavity of the sacrum and coccyx downward and forward, the base of the sacrum in well-formed female bodies being nearly four inches above the upper border of the symphysis pubis, and the apex of the coccyx a little more than half an inch above its lower border. In consequence of this obliquity of the pelvis the line of gravity of the head, which passes through the middle of the odontoid process of the axis and through the points of junction of the curves of the vertebral column to the sacro-vertebral angle, descends toward the front of the cavity, so that it bisects a line drawn transversely through the middle of the heads of the thigh-bones. And thus the centre of gravity of the head is placed immediately over the heads of the thigh-bones on which the trunk is supported.

Axes of the Pelvis (Fig. 125).—The plane of the inlet of the true pelvis will be represented by a line drawn from the base of the sacrum to the upper margin of the symphysis pubis. A line carried at right angles with this at its middle would correspond at one extremity with the umbilicus, and at the other with the middle of the coccyx: the axis of the inlet is therefore directed downward and backward. The axis of the outlet, produced upward, would touch the base of the sacrum, and is therefore directed downward and forward. The axis of the cavity is curved like the cavity itself: this curve corresponds to the concavity of the sacrum and coccyx, the extremities being indicated by the central points of the inlet and outlet. A knowledge of the direction of these axes serves to explain the course of the foetus in its passage through the pelvis during parturition. It is also important to the surgeon, as indicating the direction of the force required in the removal of calculi from the bladder by the sub-pubic operation, and as determining the direction in which instruments should be used in operations upon the pelvic viscera.

¹ The measurements of the pelvis given above are, I believe, fairly accurate, but different measurements are given by various authors, no doubt due in a great measure to differences in the physique and stature of the population from whom the measurements have been taken. The accompanying chart has been formulated to show the measurements of the pelvis which are adopted by many obstetricians.—ED.

	A. P.	Obl.	Tr.
Inlet	4	4½	5
Cavity	4½	4½	4½
Outlet	5	4½	4

Differences between the Male and the Female Pelvis.—The *female* pelvis, looked at as a whole, is distinguished from the *male* by the bones being more delicate, by its width being greater and its depth smaller. The whole pelvis is less massive, and its bones are lighter and more slender, and its muscular impressions are slightly marked. The iliac fossæ are shallow, and the anterior iliac spines widely separated; hence the greater prominence of the hips. The *inlet* in the female is larger than in the male; it is more nearly circular, and the sacro-vertebral angle projects less forward. The *cavity* is shallower and wider; the sacrum is shorter, wider, and less curved; the obturator foramina are triangular, and smaller in size than in the male. The *outlet* is larger and the coccyx more movable. The spines of the ischia project less inward. The tuberosities of the ischia and the acetabula are wider apart. The *pubic arch* is wider and more rounded than in the male, where it is an angle rather than an arch. In consequence of this the width of the fore part of the pelvic outlet is much increased and the passage of the foetal head facilitated.

FIG. 125.—Vertical section of the pelvis, with lines indicating the axis of the pelvis.

The size of the pelvis varies, not only in the two sexes, but also in different members of the same sex. This does not appear to be influenced in any way by the height of the individual. Women of short stature, as a rule, have broad pelvises. Occasionally the pelvis is equally contracted in all its dimensions, so much so that all its diameters measure an inch less than the average, and this even in women of average height and otherwise well formed. The principal divergences, however, are found at the inlet, and affect the relation of the antero-posterior to the transverse diameter. Thus we may have a pelvis the inlet of which is elliptical either in a transverse or antero-posterior direction; the transverse diameter in the former and the antero-posterior in the latter greatly exceeding the other diameters. Again, the inlet of the pelvis in some instances is seen to be almost circular.

The same differences are found in various races. European women are said to have the most roomy pelvises. That of the negress is smaller, circular in shape, and with a narrow pubic arch. The Hottentots and Bushwomen possess the smallest pelvises.

In the *fœtus* and for several years after birth the pelvis is small in proportion to that of the adult. The cavity is deep, and the projection of the sacro-vertebral angle less marked. The generally accepted opinion that the female pelvis does not acquire its sexual characters until after puberty has been shown by recent observations¹ to be erroneous, the characteristic differences between the male and female pelvis being distinctly indicated as early as the fourth month of foetal life.

Surface Form.—The pelvic bones are so thickly covered with muscles that it is only at certain points that they approach the surface and can be felt through the skin. In front, the anterior superior spinous process is easily to be recognized; a portion of it is subcutaneous, and in thin subjects may be seen to stand out as a prominence at the outer extremity of the fold of the groin. In fat subjects its position is marked by an oblique depression amongst the surrounding fat, at the bottom of which the bony process may be felt. Proceeding upward and outward from this process, the crest of the ilium may be traced throughout its whole length, sinuously curved. It is represented, in muscular subjects, on the surface, by a groove or furrow, the *iliac furrow*, caused by the projection of fleshy fibres of the External oblique muscle of the abdomen; the iliac furrow lies slightly below the level of the crest. It terminates behind in the posterior superior spinous process, the position of which is indicated by a slight depression on a level with the spinous process of the second sacral vertebra. Between the two posterior superior spinous processes, but at a lower level, is to be felt the spinous process of the third sacral vertebra (see page 53). Another part of the bony pelvis which is easily accessible to the

¹ Fehling, *Zeitschr. für Geburt. u. Gynaek.*, Bd. ix. und x.; and Arthur Thomson, *Journal of Anatomy and Physiology*, vol. xxxiii.

touch is the tuberosity of the ischium, situated beneath the gluteal fold, and, when the hip is flexed, easily to be felt, as it is then to a great extent uncovered by muscle. Finally, the spine of the os pubis can always be readily felt, and constitutes an important surgical guide, especially in connection with the subject of hernia. It is nearly in the same horizontal line with the upper edge of the great trochanter. In thin subjects it is very apparent, but in the obese it is obscured by the pubic fat. It can, however, be detected by following up the tendon of origin of the Adductor longus muscle.

Surgical Anatomy.—There is arrest of development in the bones of the pelvis in cases of extroversion of the bladder; the anterior part of the pelvic girdle being deficient, the bodies of the pubic bones imperfectly developed, and the symphysis absent. The pubic bones are separated to the extent of from two to four inches, the superior rami shortened and directed forward, and the obturator foramen diminished in size, narrowed, and turned outward. The iliac bones are straightened out more than normal. The sacrum is very peculiar. The lateral curve, instead of being concave, is flattened out or even convex, with the ilio-sacral facets turned more outward than normal, while the vertical curve is straightened.¹

Fractures of the pelvis are divided into fractures of the false pelvis and of the true pelvis. Fractures of the false pelvis vary in extent: a small portion of the crest may be broken or one of the spinous processes may be torn off, and this may be the result of muscular action; or the bone may be extensively comminuted. This latter accident is the result of some crushing violence, and may be complicated with fracture of the true pelvis. These cases may be accompanied by injury to the intestine as it lies in the hollow of the bone, or to the iliac vessels as they course along the margin of the true pelvis. Fractures of the true pelvis generally occur through the ascending ramus of the os pubis and the ramus of the ischium, as this is the weakest part of the bony ring, and may be caused either by crushing violence applied in an antero-posterior direction, when the fracture occurs from direct force, or by compression laterally, when the acetabula are pressed together, and the bone gives way in the same place from indirect violence. Occasionally the fracture may be double, occurring on both sides of the body. It is in these cases that injury to the contained viscera is liable to take place: the urethra, the bladder, the rectum, the vagina in the female, the small intestines, and even the uterus, have all been lacerated by a displaced fragment. Fractures of the acetabulum are occasionally met with: either a portion of the rim may be broken off, or a fracture may take place through the bottom of the cavity, and the head of the femur driven inward and project into the pelvic cavity. Separation of the Y-shaped cartilage at the bottom of the acetabulum may also occur in the young subject, separating the bone into its three anatomical portions.

The sacrum is occasionally, but rarely, broken by direct violence—i. e., blows, kicks, or falls on the part. The lesion may be complicated with injury to the nerves of the sacral plexus, leading to paralysis and loss of sensation in the lower extremity, or to incontinence of feces from paralysis of the sphincter ani.

The pelvic bones often undergo important deformity in rickets, the effect of which in the adult woman may interfere seriously with childbearing. The deformity is due mainly to the weight of the spine and trunk, which presses on the sacro-vertebral angle and greatly increases it, so that the antero-posterior diameter of the pelvis is diminished. But, in addition to this, the weight of the viscera on the venter ilii causes them to expand and the tuberosities of the ischia to be incurved. In osteomalacia also great deformity may occur. The weight of the trunk causes an increase in the sacro-vertebral angle and a lessening of the antero-posterior diameter of the inlet, and at the same time the pressure of the acetabula on the heads of the thigh-bones causes these cavities, with the adjacent bone, to be pushed upward and backward, so that the oblique diameters of the pelvis are also diminished, and the cavity of the pelvis assumes a triradiate shape, with the symphysis pubis pushed forward.

THE THIGH.

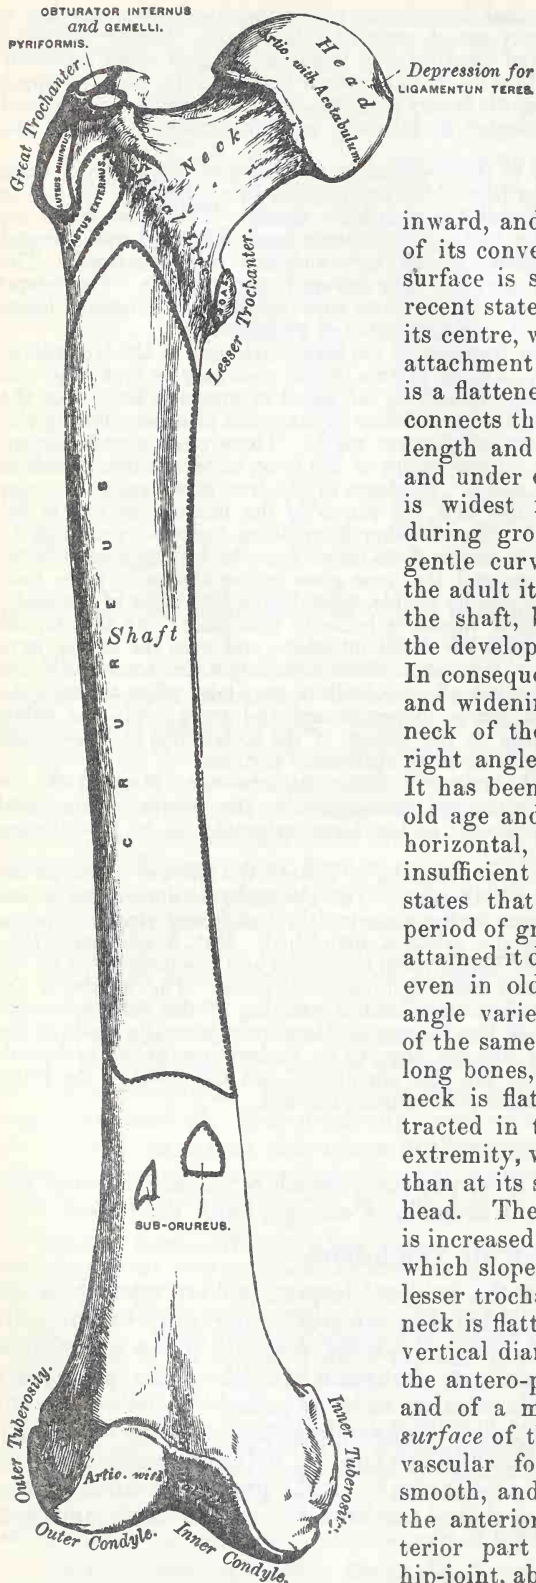

The **Thigh** is that portion of the lower extremity which is situated between the pelvis and the knee. It consists in the skeleton of a single bone, the femur.

The Femur, or Thigh-Bone.

The **Femur** (*femur*, the thigh) is the longest,² largest, and strongest bone in the skeleton, and almost perfectly cylindrical in the greater part of its extent. In the erect posture it is not vertical, being separated from its fellow above by a considerable interval, which corresponds to the entire breadth of the pelvis, but inclining gradually downward and inward, so as to approach its fellow toward its lower part, for the purpose of bringing the knee-joint near the line of gravity of the body. The degree of this inclination varies in different persons, and is greater in the female than the male, on account of the greater breadth of the pelvis. The femur, like other long bones, is divisible into a shaft and two extremities.

¹ Wood. *Heath's Dictionary of Practical Surgery*, i., 426.

² In a man six feet high it measures eighteen inches—one-fourth of the whole body.

The **Upper Extremity** presents for examination a head, a neck, and a great and lesser trochanters.

The head, which is globular, and forms rather more than a hemisphere, is directed upward, inward, and a little forward, the greater part of its convexity being above and in front. Its surface is smooth, coated with cartilage in the recent state, except at a little behind and below its centre, where is an ovoid depression, for the attachment for the ligamentum teres. The **neck** is a flattened pyramidal process of bone which connects the head with the shaft. It varies in length and obliquity at various periods of life and under different circumstances. The angle is widest in infancy, and becomes lessened during growth, so that at puberty it forms a gentle curve from the axis of the shaft. In the adult it forms an angle of about 130° with the shaft, but varies in inverse proportion to the development of the pelvis and the stature. In consequence of the prominence of the hips and widening of the pelvis in the female, the neck of the thigh-bone forms more nearly a right angle with the shaft than it does in man. It has been stated that the angle diminishes in old age and the direction of the neck becomes horizontal, but this statement is founded on insufficient evidence. Sir George Humphry states that the angle decreases during the period of growth, but after full growth has been attained it does not usually undergo any change, even in old age. He further states that the angle varies considerably in different persons of the same age. It is smaller in short than in long bones, and when the pelvis is wide.¹ The neck is flattened from before backward, contracted in the middle, and broader at its outer extremity, where it is connected with the shaft, than at its summit, where it is attached to the head. The vertical diameter of the outer half is increased by the thickening of the lower edge, which slopes downward to join the shaft at the lesser trochanter, so that the outer half of the neck is flattened from before backward, and its vertical diameter measures one-third more than the antero-posterior. The inner half is smaller and of a more circular shape. The *anterior surface* of the neck is perforated by numerous vascular foramina. The *posterior surface* is smooth, and is broader and more concave than the anterior; it gives attachment to the posterior part of the capsular ligament of the hip-joint, about half an inch above the posterior

FIG. 126.—Right femur. Anterior surface.

¹ *Journal of Anatomy and Physiology.*

intertrochanteric line. The *superior border* is short and thick, and terminates externally at the great trochanter; its surface is perforated by large foramina. The *inferior border*, long and narrow, curves a little backward, to terminate at the lesser trochanter.

The **Trochanters** (τροχῶν, to run or roll) are prominent processes of bone which afford leverage to the muscles which rotate the thigh on its axis. They are two in number, the great and the lesser.

The **Great Trochanter** is a large, irregular, quadrilateral eminence, situated at the outer side of the neck, at its junction with the upper part of the shaft. It is directed a little outward and backward, and in the adult is about three-quarters of an inch lower than the head. It presents for examination two surfaces and four borders. The *external surface*, quadrilateral in form, is broad, rough, convex, and marked by a prominent diagonal impression, which extends from the posterior superior to the anterior inferior angle, and serves for the attachment of the tendon of the Gluteus medius. Above the impression is a triangular surface, sometimes rough for part of the tendon of the same muscle, sometimes smooth for the interposition of a bursa between that tendon and the bone. Below and behind the diagonal line is a smooth, triangular surface, over which the tendon of the Gluteus maximus muscle plays, a bursa being interposed. The *internal surface* is of much less extent than the external, and presents at its base a deep depression, the *digital or trochanteric fossa*, for the attachment of the tendon of the Obturator externus muscle; above and in front of this an impression for the attachment of the Obturator internus and Gemelli. The *superior border* is free; it is thick and irregular, and marked near the centre by an impression for the attachment of the Piriformis. The *inferior border* corresponds to the point of junction of the base of the trochanter with the outer surface of the shaft; it is marked by a rough, prominent, slightly curved ridge, which gives attachment to the upper part of the Vastus externus muscle. The *anterior border* is prominent, somewhat irregular, as well as the surface of bone immediately below it; it affords attachment at its outer part to the Gluteus minimus. The *posterior border* is very prominent, and appears as a free, rounded edge, which forms the back part of the digital fossa.

The **Lesser Trochanter** is a conical eminence which varies in size in different subjects; it projects from the lower and back part of the base of the neck. Its base is triangular, and connected with the adjacent parts of the bone by three well-marked borders: two of these are above—the *internal* continuous with the lower border of the neck, the *external* with the posterior intertrochanteric line—while the *inferior border* is continuous with the middle division of the linea aspera. Its summit, which is directed inward and backward, is rough, and gives insertion to the tendon of the Ilio-psoas. The Iliacus is also inserted into the shaft below the lesser trochanter between the Vastus internus in front and the Pectineus behind.

A well-marked prominence of variable size, which projects from the upper and front part of the neck at its junction with the great trochanter, is called the *tubercle of the femur*; it is the point of meeting of five muscles: the Gluteus minimus externally, the Vastus externus below, and the tendon of the Obturator internus and Gemelli above. Running obliquely downward and inward from the tubercle is the *spiral line* of the femur, or *anterior intertrochanteric line*; it winds round the inner side of the shaft, below the lesser trochanter, and terminates in the linea aspera, about two inches below this eminence. Its upper half is rough, and affords attachment to the ilio-femoral ligament of the hip-joint; its lower half is less prominent, and gives attachment to the upper part of the Vastus internus. Running obliquely downward and inward from the summit of the great trochanter on the posterior surface of the neck is a very prominent, well-marked ridge, the *posterior intertrochanteric line*. Its upper half forms the posterior border of the great trochanter, and its lower half runs downward and inward to the upper and back part of the lesser trochanter. A slight ridge sometimes commences about the

FIG. 127.—Right femur. Posterior surface.

middle of the posterior intertrochanteric line, and passes vertically downward for about two inches along the back part of the shaft: it is called the *linea quadrati*, and gives attachment to the Quadratus femoris and a few fibres of the Adductor magnus muscles.¹

The **Shaft**, almost cylindrical in form, is a little broader above than in the centre, and somewhat flattened below, from before backward. It is slightly arched, so as to be convex in front and concave behind, where it is strengthened by a prominent longitudinal ridge, the *linea aspera*. It presents for examination three borders, separating three surfaces. Of the three borders, one, the *linea aspera*, is posterior; the other two are placed laterally.

The *linea aspera* (Fig. 127) is a prominent longitudinal ridge or crest, on the middle third of the bone, presenting an external lip, an internal lip, and a rough intermediate space. Above, this crest is prolonged by three ridges. The most external one is very rough, and is continued almost vertically upward to the base of the great trochanter. It is sometimes termed the *gluteal ridge*, and gives attachment to part of the Gluteus maximus muscle; its upper part is often elongated into a roughened crest, on which is a more or less well-marked, rounded tubercle, a rudimentary third trochanter. The middle ridge, the least distinct, is continued to the base of the trochanter minor, and the internal one is lost above in the spiral line of the femur. Below, the *linea aspera* is prolonged by two ridges, which enclose between them a triangular space, the *popliteal surface*, upon which rests the popliteal artery. Of these two ridges, the outer one is the more prominent, and de-

¹ Generally there is merely a slight thickening about the centre of the intertrochanteric line, marking the point of attachment of the Quadratus femoris. This is termed by some anatomists the *tubercle of the Quadratus*.

scends to the summit of the outer condyle. The inner one is less marked, especially at its upper part, where it is crossed by the femoral artery. It terminates, below, at the summit of the internal condyle, in a small tubercle, the *Adductor tubercle*, which affords attachment to the tendon of the Adductor magnus.

To the inner lip of the linea aspera and its inner prolongation above and below is attached the Vastus internus, and to the outer lip and its outer prolongation above is attached the Vastus externus. The Adductor magnus is attached to the linea aspera, to its outer prolongation above and its inner prolongation below. Between the Vastus externus and the Adductor magnus are attached two muscles—viz. the Gluteus maximus above, and the short head of the Biceps below. Between the Adductor magnus and the Vastus internus four muscles are attached: the Iliacus and Pectineus above, the Adductor brevis and Adductor longus below. The linea aspera is perforated a little below its centre by the nutrient canal, which is directed obliquely upward.

The *two lateral borders* of the femur are only slightly marked, the outer one extending from the anterior inferior angle of the great trochanter to the anterior extremity of the external condyle; the inner one from the spiral line, at a point opposite the trochanter minor, to the anterior extremity of the internal condyle. The internal border marks the limit of attachment of the Crureus muscle internally.

The **anterior surface** includes that portion of the shaft which is situated between the two lateral borders. It is smooth, convex, broader above and below than in the centre, slightly twisted, so that its upper part is directed forward and a little outward, its lower part forward and a little inward. To the upper three-fourths of this surface the Crureus is attached; the lower fourth is separated from the muscle by the intervention of the synovial membrane of the knee-joint and a bursa, and affords attachment to the Subcrureus to a small extent. The *external surface* includes the portion of bone between the external border and the outer lip of the linea aspera: it is continuous above with the outer surface of the great trochanter, below with the outer surface of the external condyle; to its upper three-fourths is attached the outer portion of the Crureus muscle. The *internal surface* includes the portion of bone between the internal border and the inner lip of the linea aspera; it is continuous above with the lower border of the neck, below with the inner side of the internal condyle: it is covered by the Vastus externus muscle.

The **Lower Extremity**, larger than the upper, is of a cuboid form, flattened from before backward, and divided into two large eminences, the *condyles* (κόνδυλος, a knuckle), by an interval which presents a smooth depression in front called the *trochlea*, and a notch of considerable size behind—the *intercondyloid notch*. The *external condyle* is the more prominent anteriorly, and is the broader both in the antero-posterior and transverse diameters. The *internal condyle* is the narrower, longer, and more prominent inferiorly. This difference in the length of the two condyles is only observed when the bone is perpendicular, and depends upon the obliquity of the thigh-bones, in consequence of their separation above at the articulation with the pelvis. If the femur is held obliquely, the surfaces of the two condyles will be seen to be nearly horizontal. The two condyles are directly continuous in front, and form a smooth trochlear surface, which articulates with the patella. It presents a median groove, which extends downward and backward to the intercondyloid notch; and two lateral convexities, of which the external is the broader, more prominent, and prolonged farther upward upon the front of the outer condyle. The external border of this articular surface is also more prominent, and ascends higher than the internal one. The intercondyloid notch lodges the crucial ligaments; it is bounded laterally by the opposed surfaces of the two condyles, and in front by the lower end of the shaft.

Outer Condyle.—The *outer surface* of the external condyle presents, a little behind its centre, an eminence, the *outer tuberosity*; it is less prominent than the inner tuberosity, and gives attachment to the external lateral ligaments of the knee. Immediately beneath it is a groove which commences at a depression a

little behind the centre of the lower border of this surface: the front part of this depression gives origin to the Popliteus muscle, the tendon of which is lodged in the groove during flexion of the knee. The groove is smooth, covered with cartilage in the recent state, and runs upward and backward to the posterior extremity of the condyle. The *inner surface* of the outer condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its posterior part, to the anterior crucial ligament. The *inferior surface* is convex, smooth, and broader than that of the internal condyle. The posterior extremity is convex and smooth: just above and to the outer side of the articular surface is a depression for the tendon of the outer head of the Gastrocnemius, above which is the origin of the Plantaris.

Inner Condyle.—The *inner surface* of the inner condyle presents a convex eminence, the *inner tuberosity*, rough for the attachment of the internal lateral ligament. The *outer side* of the inner condyle forms one of the lateral boundaries of the intercondyloid notch, and gives attachment, by its anterior part, to the posterior crucial ligament. Its *inferior* or *articular surface* is convex, and presents a less extensive surface than the external condyle. Just above the articular surface of the condyle, behind, is a depression for the tendon of origin of the inner head of the Gastrocnemius.

Structure.—The shaft of the femur is a cylinder of compact tissue, hollowed by a large medullary canal. The cylinder is of great thickness and density in the middle third of the shaft, where the bone is narrowest and the medullary canal well formed; but above and below this the cylinder gradually becomes thinner, owing to a separation of the layers of the bone into cancelli, which project into the medullary canal and finally obliterate it, so that the upper and lower ends of the shaft, and the articular extremities more especially, consist of cancellated tissue invested by a thin, compact layer.

The arrangement of the cancelli in the ends of the femur is remarkable. In the upper end they are arranged in two sets. One, starting from the top of the head, the upper surface of the neck, and the great trochanter, converge to the inner circumference of the shaft (Fig. 128); these are placed in the direction of greatest pressure, and serve to support the vertical weight of the body. The second set are planes of lamellæ intersecting the former nearly at right angles, and are situated in the line of the greatest tension—that is to say, along the lines in which the muscles and ligaments exert their traction. In the head of the bone these

FIG. 128.—Diagram showing the arrangement of the cancelli of the neck of the femur.

FIG. 129.—Calcar femorale.

planes are arranged in a curved form, in order to strengthen the bone when exposed to pressure in all directions. In the midst of the cancellous tissue of the neck is a vertical plane of compact bone, the *femoral spur* (*calcar femorale*) which commences at the point where the neck joins the shaft midway between the lesser trochanter and the internal border of the shaft of the bone, and extends in the direction of the digital fossa (Fig. 129). This materially strengthens this portion of the bone. Another point in connection with the structure of the neck of the femur requires mention, especially on account of its influence on the production of fracture in this situation. It will be noticed that a considerable portion of the great trochanter lies behind the level of the posterior surface of the neck; and if a section be made through the trochanter at this level, it will be seen that the posterior wall of the neck is prolonged into the trochanter. This prolongation is termed by Bigelow the "true neck,"¹ and forms a thin, dense plate of bone, which passes beneath the posterior intertrochanteric ridge toward the outer surface of the bone.

In the lower end the cancelli spring on all sides from the inner surface of the cylinder, and descend in a perpendicular direction to the articular surface, the cancelli being strongest and having a more accurately perpendicular course above the condyles. In addition to this, however, horizontal planes of cancellous tissue are to be seen, so that the spongy tissue in this situation presents an appearance of being mapped out into a series of rectangular areas.

Articulations.—With three bones: the os innominatum, tibia, and patella.

Development (Fig. 130).—The femur is developed by five centres: one for the shaft, one for each extremity, and one for each trochanter. Of all the long bones, except the clavicle, it is the first to show traces of ossification: this commences in the shaft, at about the seventh week of foetal life, the centres of ossification in the epiphyses appearing in the following order: First, in the lower end of the bone, at the ninth month of foetal life² (from this the condyles and tuberosities are formed); in the head at the end of the first year after birth; in the great trochanter, during the fourth year; and in the lesser trochanter, between the thirteenth and fourteenth. The order in which the epiphyses are joined to the shaft is the reverse of that of their appearance: their junction does not commence until after puberty, the lesser trochanter being first joined, then the great, then the head, and, lastly, the inferior extremity (the first in which ossification commenced), which is not united until the twentieth year.

Attachment of Muscles.—To twenty-three. To the great trochanter: the Gluteus medius, Gluteus minimus, Piriformis, Obturator internus, Obturator externus, Gemellus superior, Gemellus inferior, and Quadratus femoris. To the lesser trochanter: the Psoas magnus and the Iliacus below it. To the shaft:

FIG. 130.—Plan of the development of the femur. By five centres.

¹ Bigelow on the Hip, p. 121.

² This is said to be the only epiphysis in which ossification begins before birth; though according to some observers, the centre for the upper epiphysis of the tibia also appears before birth.

the Vastus externus, Gluteus maximus, short head of the Biceps, Vastus internus, Adductor magnus, Pectineus, Adductor brevis, Adductor longus, Crureus, and Subcrureus. To the condyles: the Gastrocnemius, Plantaris, and Popliteus.

Surface Form.—The femur is covered with muscles, so that in fairly muscular subjects the shaft is not to be detected through its fleshy covering, and the only parts accessible to the touch are the outer surface of the great trochanter and the lower expanded end of the bone. The external surface of the great trochanter is to be felt, especially in certain positions of the limb. Its position is generally indicated by a depression, owing to the thickness of the Gluteus medius and minimus, which project above it. When, however, the thigh is flexed, and especially if crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The upper border is about on a line with the spine of the os pubis, and its exact level is indicated by a line drawn from the anterior superior spinous process of the ilium, over the outer side of the hip, to the most prominent point of the tuberosity of the ischium. This is known as Nélaton's line. The outer and inner condyles of the lower extremity are easily to be felt. The outer one is more subcutaneous than the inner one, and readily felt. The tuberosity on it is comparatively little developed, but can be more or less easily recognized. The inner condyle is more thickly covered, and this gives a general convex outline to this part, especially when the knee is flexed. The tuberosity on it is easily felt, and at the upper part of the condyle the sharp tubercle for the insertion of the tendon of the Adductor magnus can be recognized without difficulty. When the knee is flexed, and the patella situated in the interval between the condyles and the upper end of the tibia, a part of the trochlear surface of the femur can be made out above the patella.

Surgical Anatomy.—There are one or two points about the ossification of the femur bearing on practice to which allusion must be made. It has been stated above that the lower end of the femur is the only epiphysis in which ossification has commenced at the time of birth. The presence of this ossific centre is, therefore, a proof, in newly-born children found dead, that the child has arrived at the full period of utero-gestation, and is always relied upon in medico-legal investigations. The position of the epiphysal line should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the cartilage-clad portion of the lower end of the bone. It is essential to bear this point in mind in performing excision of the knee, since growth in length of the femur takes place chiefly from the lower epiphysis, and any interference with the epiphysal cartilage in a young child would involve such ultimate shortening of the limb, from want of growth, as to render it almost useless. Separation of the lower epiphysis may take place up to the age of twenty, at which time it becomes completely joined to the shaft of the bone; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis of the head of the femur is of interest principally on account of its being the seat of origin of a large number of cases of tuberculous disease of the hip-joint. The disease commences in the majority of cases in the highly vascular and growing tissue in the neighborhood of the epiphysis, and from here extends into the joint.

Fractures of the femur are divided, like those of the other long bones, into fractures of the upper end; of the shaft; and of the lower end. The fractures of the upper end may be classified into (1) fracture of the neck; (2) fracture at the junction of the neck with the great trochanter; (3) fracture of the great trochanter; and (4) separation of the epiphysis, either of the head or of the great trochanter. The first of these, fracture of the neck, is usually termed intracapsular fracture, but this is scarcely a correct designation, as, owing to the attachment of the capsular ligament, the fracture may be partly within and partly without the capsule, when the fracture occurs at the lower part of the neck. It generally occurs in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of the fracture taking place in old people is in consequence of the degenerative changes which the bone has undergone. Merkel believes that it is mainly due to the absorption of the calcar femorale. These fractures are occasionally impacted. As a rule they unite by fibrous tissue, and frequently no union takes place, and the surfaces of the fracture become smooth and eburnated.

Fractures at the junction of the neck with the great trochanter are usually termed extracapsular, but this designation is also incorrect, as the fracture is partly within the capsule, owing to its attachment in front to the anterior intertrochanteric line, which is situated below the line of fracture. These fractures are produced by direct violence to the great trochanter, as from a blow or fall laterally on the hip. From the manner in which the accident is caused, the neck of the bone is driven into the trochanter, where it may remain impacted, or the trochanter may be split up into two or more fragments, and thus no fixation takes place.

Fractures of the great trochanter may be either "oblique fracture through the trochanter major, without implicating the neck of the bone" (Astley Cooper), or separation of the great trochanter. Most of the recorded cases of this latter injury occurred in young persons, and were probably cases of separation of the epiphysis of the great trochanter. Separation of the epiphysis of the head of the femur has been said to occur, but has probably never been verified by post-mortem examination.

Fractures of the shaft may occur at any part, but the most usual situation is at or near the centre of the bone. They may be caused by direct or indirect violence or by muscular action.

Fractures of the upper third of the shaft are almost always the result of indirect violence, whilst those of the lower third are the result, for the most part, of direct violence. In the middle third fractures occur from both forms of injury in about equal proportions. Fractures of the shaft are generally oblique, but they may be transverse, longitudinal, or spiral. The transverse fracture occurs most frequently in children. The fractures of the lower end of the femur include transverse fracture above the condyles, the most common; and this may be complicated by a vertical fracture between the condyles, constituting the T-shaped fracture. In these cases the popliteal artery is in danger of being wounded. Oblique fracture, separating either the internal or external condyle, and a longitudinal incomplete fracture between the condyles, may also take place.

The femur as well as the other bones of the leg are frequently the seat of acute necrosis in young children. This is no doubt due to their greater exposure to injury, which is often the exciting cause of this disease. Tumors not unfrequently are found growing from the femur: the most common forms being sarcoma, which may grow either from the periosteum or from the medullary tissue within the interior of the bone; and exostosis, which is commonly found originating in the neighborhood of the epiphysial cartilage of the lower end.

THE LEG.

The skeleton of the Leg consists of three bones: the Patella, a large sesamoid bone, placed in front of the knee; the Tibia; and the Fibula.

The Patella (Figs. 131, 132).

The **Patella** (*patella*, a small pan) is a flat, triangular bone, situated at the anterior part of the knee-joint. It is usually regarded as a sesamoid bone, developed in the tendon of the Quadriceps extensor. It resembles these bones (1) in its being developed in a tendon; (2) in its centre of ossification presenting a knotty or tuberculated outline; (3) in its structure being composed mainly of dense cancellous tissue, as in the other sesamoid bones. It serves to protect the front of the joint, and increases the leverage of the Quadriceps extensor by making it act at a greater angle. It presents an anterior and a posterior surface, three borders, and an apex.

The **anterior surface** is convex, perforated by small apertures, for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. This surface is covered, in the recent state, by an expansion from the tendon of the Quadriceps extensor, which is continuous below with the superficial fibres of the ligamentum patellæ. It is separated from the integument by a bursa. The **posterior surface** presents a smooth, oval-shaped, articular surface, covered with cartilage in the recent state, and divided into two facets by a vertical ridge, which descends from the superior border toward the inferior angle of the bone. The ridge corresponds to the groove on the trochlear surface of the femur, and the two facets to the articular surfaces of the two condyles; the outer facet, for articulation with the outer condyle, being the broader and deeper. This character serves to indicate the side to which the bone belongs. Below the articular surface is a rough, convex, non-articular depression, the lower half of which gives attachment to the ligamentum patellæ, the upper half being separated from the head of the tibia by adipose tissue.

The **superior border** is thick, and sloped from behind, downward and forward: it gives attachment to that portion of the Quadriceps extensor which is derived from the Rectus and Crureus muscles. The **lateral borders** are thinner, converging below. They give attachment to that portion of the Quadriceps extensor derived from the external and internal Vasti muscles.

The **apex** is pointed, and gives attachment to the ligamentum patellæ.

FIG. 131.—Right patella. Anterior surface.

FIG. 132.—Right patella. Posterior surface.

Structure.—It consists of a nearly uniform dense cancellous tissue covered by a thin compact lamina. The cancelli immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the posterior articular surface toward the other parts of the bone.

Development.—By a single centre, which makes its appearance, according to Bécclard, about the third year. In two instances I have seen this bone cartilaginous throughout, at a much later period (six years). More rarely, the bone is developed by two centres, placed side by side. Ossification is completed about the age of puberty.

Articulations.—With the two condyles of the femur.

Attachment of Muscles.—To four: the Rectus, Crureus, Vastus internus, and Vastus externus. These muscles, joined at their insertion, constitute the Quadriceps extensor cruris.

Surface Form.—The external surface of the patella can be seen and felt in front of the knee. In the extended position of the limb the internal border is a little more prominent than the outer, and if the Quadriceps extensor is relaxed, the bone can be moved from side to side and appears to be loosely fixed. If the joint is flexed, the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly fixed against the femur.

Surgical Anatomy.—The main surgical interest about the patella is in connection with fractures; which are of common occurrence. They may be produced by muscular action; that is to say, by violent contraction of the Quadriceps extensor while the limb is in a position of semi-flexion, so that the bone is snapped across the condyles; or by direct violence, such as falls on the knee. In the former class of cases the fracture is transverse; in the latter it may be oblique, longitudinal, stellate, or the bone variously comminuted. The principal interest in these cases attaches to their treatment. Owing to the wide separation of the fragments, and the difficulty there is in maintaining them in apposition, union takes place by fibrous tissue, and this may subsequently stretch, producing wide separation of the fragments and permanent lameness. Various plans, including opening the joint and suturing the fragments, have been advocated for overcoming this difficulty.

In the larger number of cases of fracture of the patella the knee-joint is involved, the cartilage which covers its posterior surface being also torn. In some cases of fracture from direct violence, however, this need not necessarily happen, the lesion involving only the superficial part of the bone; and, as Morris has pointed out, it is an anatomical possibility, in complete fracture, if the lesion involve only the lower and non-articular part of the bone, for it to take place without injury to the synovial membrane.

The Tibia (Figs. 133, 134).

The **Tibia** (*tibia*, a flute or pipe) is situated at the front and inner side of the leg, and, excepting the femur, is the longest and largest bone in the skeleton. It is prismoid in form, expanded above, where it enters into the knee-joint, more slightly enlarged below. In the male its direction is vertical and parallel with the bone of the opposite side; but in the female it has a slightly oblique direction downward and outward, to compensate for the oblique direction of the femur inward. It presents for examination a shaft and two extremities.

The **Upper Extremity**, or **Head**, is large, and expanded on each side into two lateral eminences, the *tuberosities*. *Superiorly*, the tuberosities present two smooth, concave surfaces, which articulate with the condyles of the femur; the internal, articular surface is longer, deeper, and narrower than the external, oval from before backward, to articulate with the internal condyle; the external one is broader and more circular, concave from side to side, but slightly convex from before backward, especially at its posterior part, where it is prolonged on to the posterior surface for a short distance, to articulate with the external condyle. Between the two articular surfaces, and nearer the posterior than the anterior aspect of the bone, is an eminence, the *spinous process* of the tibia, surmounted by a prominent tubercle on each side, on to the lateral aspect of which the facets just described are prolonged; in front and behind the spinous process is a rough depression for the attachment of the anterior and posterior crucial ligaments and the semilunar fibro-cartilages. The *anterior surfaces* of the tuberosities are continuous with one another, forming a single large surface, which is somewhat

flattened: it is triangular, broad above, and perforated by large vascular foramina; narrow below, where it terminates in a prominent oblong elevation of large size, the *tubercle* of the tibia; the lower half of this tubercle is rough, for the attachment of the ligamentum patellæ; the upper half presents a smooth facet supporting, in the recent state, a bursa which separates the ligament from the bone. *Posteriorly* the tuberosities are separated from each other by a shallow depression, the *popliteal notch*, which gives attachment to part of the posterior crucial ligament and part of the posterior ligament of the knee-joint. The *inner tuberosity* presents posteriorly a deep transverse groove, for the insertion of one of the fasciculi of the tendon of the Semi-membranosus. Its *lateral surface* is convex, rough, and prominent: it gives attachment to the internal lateral ligament. The *outer tuberosity* presents posteriorly a flat articular facet, nearly circular in form, directed downward, backward, and outward, for articulation with the fibula. Its lateral surface is convex and rough, more prominent in front than the internal: it presents a prominent rough eminence, situated on a level with the upper border of the tubercle of the tibia at the junction of its anterior and outer surfaces, for the attachment of the ilio-tibial band. Just below this the Extensor longus digitorum and a slip from the Biceps are attached.

The *Shaft* of the tibia is of a triangular prismoid form, broad above, gradually decreasing in size to its most slender part, at the commencement of its lower fourth, where fracture most frequently occurs; it then enlarges again toward its lower extremity. It presents for examination three borders and three surfaces.

The *anterior border*, the most prominent of the three, is called the *crest of the tibia*, or, in popular language, the *shin*; it commences above at the tubercle, and terminates below

FIG. 133.—Bones of the right leg. Anterior surface.

FIG. 134.—Bones of the right leg. Posterior surface.

ticus, Extensor proprius hallucis, Extensor longus digitorum.

The posterior surface (Fig. 134) presents, at its upper part, a prominent ridge, the *oblique line* of the tibia, which extends from the back part of the articular

at the anterior margin of the inner malleolus. This border is very prominent in the upper two-thirds of its extent, smooth and rounded below. It presents a very flexuous course, being usually curved outward above and inward below; it gives attachment to the deep fascia of the leg.

The **internal border** is smooth and rounded above and below, but more prominent in the centre; it commences at the back part of the inner tuberosity, and terminates at the posterior border of the internal malleolus; its upper part gives attachment to the internal lateral ligament of the knee to the extent of about two inches, and to some fibres of the Popliteus muscle; its middle third to some fibres of the Soleus and Flexor longus digitorum muscles.

The **external border**, or **interosseous ridge**, is thin and prominent, especially its central part, and gives attachment to the interosseous membrane; it commences above in front of the fibular articular facet, and bifurcates below, to form the boundaries of a triangular rough surface, for the attachment of the interosseous ligament connecting the tibia and fibula.

The **internal surface** is smooth, convex, and broader above than below: its upper third, directed forward and inward, is covered by the aponeurosis derived from the tendon of the Sartorius, and by the tendons of the Gracilis and Semitendinosus, all of which are inserted nearly as far forward as the anterior border; in the rest of its extent it is subcutaneous.

The **external surface** is narrower than the internal; its upper two-thirds presents a shallow groove for the attachment of the Tibialis anticus muscle; its lower third is smooth, convex, curves gradually forward to the anterior aspect of the bone, and is covered from within outward by the tendons of the following muscles: Tibialis an-

facet for the fibula obliquely downward, to the internal border, at the junction of its upper and middle thirds. It marks the lower limit for the insertion of the Popliteus muscle, and serves for the attachment of the popliteal fascia and part of the Soleus, Flexor longus digitorum, and Tibialis posticus muscles; the triangular concave surface, above and to the inner side of this line, gives attachment to the Popliteus muscle. The middle third of the posterior surface is divided by a vertical ridge into two lateral halves: the ridge is well marked at its commencement at the oblique line, but becomes gradually indistinct below; the inner and broader half gives attachment to the Flexor longus digitorum, the outer and narrower to part of the Tibialis posticus. The remaining part of the bone presents a smooth surface covered by the Tibialis posticus, Flexor longus digitorum, and Flexor longus hallucis muscles. Immediately below the oblique line is the medullary foramen, which is large and directed obliquely downward.

The **Lower Extremity**, much smaller than the upper, presents five surfaces; it is prolonged downward, on its inner side, to a strong process, the *internal malleolus*. The *inferior surface* of the bone is quadrilateral, and smooth for articulation with the astragalus. This surface is concave from before backward, and broader in front than behind. It is traversed from before backward by a slight elevation, separating two lateral depressions. It is narrow internally, where the articular surface becomes continuous with that on the inner malleolus. The *anterior surface* of the lower extremity is smooth and rounded above, and covered by the tendons of the Extensor muscles of the toes; its lower margin presents a rough transverse depression, for the attachment of the anterior ligament of the ankle-joint; the *posterior surface* presents a superficial groove directed obliquely downward and inward, continuous with a similar groove on the posterior surface of the astragalus, and serving for the passage of the tendon of the Flexor longus hallucis; the *external surface* presents a triangular rough depression for the attachment of the inferior interosseous ligament, connecting it with the fibula; the lower part of this depression is smooth, covered with cartilage in the recent state, and articulates with the fibula. This surface is bounded by two prominent borders, continuous above with the interosseous ridge; they afford attachment to the anterior and posterior inferior tibio-fibular ligaments. The *internal surface* of the lower extremity is prolonged downward to form a strong pyramidal process, flattened from without inward—the *internal malleolus*. The *inner surface* of this process is convex and subcutaneous; its *outer surface* is smooth and slightly concave, and articulates with the astragalus; its *anterior border* is rough, for the attachment of the anterior fibres of the internal lateral or Deltoid ligament; its *posterior border* presents a broad and deep groove, directed obliquely downward and inward, which is occasionally double: this groove transmits the tendons of the Tibialis posticus and Flexor longus digitorum muscles. The *summit* of the internal malleolus is marked by a rough depression behind, for the attachment of the internal lateral ligament of the ankle-joint.

Structure.—Like that of the other long bones. At the junction of the middle and lower third, where the bone is smallest, the wall of the shaft is thicker than in other parts, in order to compensate for the smallness of the calibre of the bone.

FIG. 135.—Plan of the development of the tibia. By three centres.

Development.—By *three* centres (Fig. 135): one for the shaft, and one for each extremity. Ossification commences in the centre of the shaft about the seventh week, and gradually extends toward either extremity. The centre for the upper epiphysis appears before or shortly after birth; it is flattened in form, and has a thin, tongue-shaped process in front which forms the tubercle. That for the lower epiphysis appears in the second year. The lower epiphysis joins the shaft at about the eighteenth, and the upper one about the twentieth, year. Two additional centres occasionally exist—one for the tongue-shaped process of the upper epiphysis, which forms the tubercle, and one for the inner malleolus.

Articulations.—With three bones: the femur, fibula, and astragalus.

Attachment of Muscles.—To twelve: to the inner tuberosity, the Semimembranosus; to the outer tuberosity, the Tibialis anticus and Extensor longus digitorum and Biceps; to the shaft, its internal surface, the Sartorius, Gracilis, and Semitendinosus; to its external surface, the Tibialis anticus; to its posterior surface, the Popliteus, Soleus, Flexor longus digitorum, and Tibialis posticus; to the tubercle, the ligamentum patellæ, by which the Quadriceps extensor muscle is inserted into the tibia. In addition to these muscles, the Tensor fasciæ femoris is inserted indirectly into the tibia, through the ilio-tibial band, and the Peroneus longus occasionally derives a few fibres of origin from the outer tuberosity.

Surface Form.—A considerable portion of the tibia is subcutaneous and easily to be felt. At the upper extremity the tuberosities are to be recognized just below the knee. The internal one is broad and smooth, and merges into the subcutaneous surface of the shaft below. The external one is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, may be felt a prominent tubercle for the insertion of the ilio-tibial band. In front of the upper end of the bone, between the tuberosities, is the tubercle of the tibia, forming an oval eminence which is continuous below with the anterior border or crest of the bone. This border can be felt, forming the prominence of the shin, in the upper two-thirds of its extent as a sharp and flexuous ridge, curved outward above and inward below. In the lower third of the leg the border disappears, and the bone is concealed by the tendons of the muscles on the front of the leg. Internal to the anterior border is to be felt the broad internal surface of the tibia, slightly encroached upon by the muscles in front and behind. It commences above at the wide expanded inner tuberosity, and terminates below at the internal malleolus. The internal malleolus is a broad prominence situated on a higher level and somewhat farther forward than the external malleolus. It overhangs the inner border of the arch of the foot. Its anterior border is nearly straight; its posterior border presents a sharp edge, which forms the inner margin of the groove for the tendon of the Tibialis posticus muscle.

The Fibula (Figs. 133, 134).

The **Fibula** (*fibula*, a clasp) is situated at the outer side of the leg. It is the smaller of the two bones, and, in proportion to its length, the most slender of all the long bones; it is placed on the outer side of the tibia, with which it is connected above and below. Its upper extremity is small, placed toward the back of the head of the tibia and below the level of the knee-joint, and excluded from its formation; the lower extremity inclines a little forward, so as to be on a plane anterior to that of the upper end, projects below the tibia, and forms the outer ankle. It presents for examination a shaft and two extremities.

The **Upper Extremity**, or **Head**, is of an irregular quadrate form, presenting above a flattened articular facet, directed upward, forward, and inward, for articulation with a corresponding facet on the external tuberosity of the tibia. On the outer side is a thick and rough prominence, continued behind into a pointed eminence, the *styloid process*, which projects upward from the posterior part of the head. The *prominence* gives attachment to the tendon of the Biceps muscle and to the long external lateral ligament of the knee, the ligament dividing the tendon into two parts. The *summit* of the styloid process gives attachment to the short external lateral ligament. The remaining part of the circumference of the head is rough, for the attachment of muscles and ligaments. It presents in front a tubercle for the origin of the upper and anterior part of the Peroneus longus, and the adjacent surface gives attachment to the anterior superior tibio-fibular ligament; and behind, another tubercle for the attachment of the posterior superior tibio-fibular ligament and the upper fibres of the Soleus muscle.

The **shaft** presents four borders—the antero-external, the antero-internal, the postero-external, and the postero-internal; and four surfaces—anterior, posterior, internal, and external.

The **antero-external border** commences above in front of the head, runs vertically downward to a little below the middle of the bone, and then, curving somewhat outward, bifurcates so as to embrace the triangular subcutaneous surface immediately above the outer surface of the external malleolus. This border gives attachment to an intermuscular septum, which separates the extensor muscles on the anterior surface of the leg from the Peroneus longus and brevis muscles on the outer surface.

The **antero-internal border**, or **interosseous ridge**, is situated close to the inner side of the preceding, and runs nearly parallel with it in the upper third of its extent, but diverges from it so as to include a broader space in the lower two-thirds. It commences above, just beneath the head of the bone (sometimes it is quite indistinct for about an inch below the head), and terminates below at the apex of a rough triangular surface immediately above the articular facet of the external malleolus. It serves for the attachment of the interosseous membrane, which separates the extensor muscles in front from the flexor muscles behind.

The **postero-external border** is prominent; it commences above at the base of the styloid process, and terminates below in the posterior border of the outer malleolus. It is directed outward above, backward in the middle of its course, backward and a little inward below, and gives attachment to an aponeurosis which separates the Peronei muscles on the outer surface of the shaft from the flexor muscles on its posterior surface.

The **postero-internal border**, sometimes called the *oblique line*, commences above at the inner side of the head, and terminates by becoming continuous with the antero-internal border or interosseous ridge at the lower fourth of the bone. It is well marked and prominent at the upper and middle parts of the bone. It gives attachment to an aponeurosis which separates the Tibialis posticus from the Soleus above and the Flexor longus hallucis below.

The **anterior surface** is the interval between the antero-external and antero-internal borders. It is extremely narrow and flat in the upper third of its extent; broader and grooved longitudinally in its lower third; it serves for the attachment of three muscles, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis.

The **external surface** is the space between the antero-external and postero-external borders. It is much broader than the preceding, and often deeply grooved, is directed outward in the upper two-thirds of its course, backward in the lower third, where it is continuous with the posterior border of the external malleolus. This surface is completely occupied by the Peroneus longus and brevis muscles.

The **internal surface** is the interval included between the antero-internal and the postero-internal borders. It is directed inward, and is grooved for the attachment of the Tibialis posticus muscle.

The **posterior surface** is the space included between the postero-external and the postero-internal borders; it is continuous below with the rough triangular surface above the articular facet of the outer malleolus; it is directed backward above, backward and inward at its middle, directly inward below. Its upper third is rough, for the attachment of the Soleus muscle; its lower part presents a triangular rough surface, connected to the tibia by a strong interosseous ligament, and between these two points the entire surface is covered by the fibres of origin of the Flexor longus hallucis muscle. At about the middle of this surface is the nutrient foramen, which is directed downward.

The **Lower Extremity**, or **external malleolus**, is of a pyramidal form, somewhat flattened from without inward, and is longer, and descends lower than the internal malleolus. Its *external surface* is convex, subcutaneous, and continuous with the triangular (also subcutaneous) surface on the outer side of the shaft. The *internal surface* presents in front a smooth triangular facet, broader above than below, and

convex from above downward, which articulates with a corresponding surface on the outer side of the astragalus. Behind and beneath the articular surface is a rough depression which gives attachment to the posterior fasciculus of the external lateral ligament of the ankle. The *anterior border* is thick and rough, and marked below by a depression for the attachment of the anterior fasciculus of the external lateral ligament. The *posterior border* is broad and marked by a shallow groove, for the passage of the tendons of the Peroneus longus and brevis muscles. The *summit* is rounded, and gives attachment to the middle fasciculus of the external lateral ligament.

In order to distinguish the side to which the bone belongs, hold it with the lower extremity downward and the broad groove for the Peronei tendons backward—*i. e.* toward the holder: the triangular subcutaneous surface will then be directed to the side to which the bone belongs.

Articulations.—With two bones: the tibia and astragalus.

Development.—By *three* centres (Fig. 136): one for the shaft, and one for each extremity. Ossification commences in the shaft about the eighth week of foetal life, a little later than in the tibia, and extends gradually toward the extremities. At birth both ends are cartilaginous. Ossification commences in the lower end in the second year, and in the upper one about the fourth year. The lower epiphysis, the first in which ossification commences, becomes united to the shaft about the twentieth year; the upper epiphysis joins about the twenty-fifth year. Ossification appearing first in the lower epiphysis is contrary to the rule which prevails with regard to the commencement of ossification in epiphyses—*viz.* that that epiphysis toward which the nutrient artery is directed commences to ossify last; but it follows the rule which prevails with regard to the union of epiphyses, by uniting first.

FIG. 136.—Plan of the development of the fibula. By three centres.

Attachment of Muscles.—To nine: to the head, the Biceps, Soleus, and Peroneus longus; to the shaft, its anterior surface, the Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis; to the internal surface, the Tibialis posterior; to the posterior surface, the Soleus and Flexor longus hallucis; to the external surface, the Peroneus longus and brevis.

Surface Form.—The only parts of the fibula which are to be felt are the head and the lower part of the external surface of the shaft and the external malleolus. The head is to be seen and felt behind and to the outer side of the outer tuberosity of the tibia. It presents a small, prominent triangular eminence slightly above the level of the tubercle of the tibia. The external malleolus presents a narrow elongated prominence, situated on a plane posterior to the internal malleolus and reaching to a lower level. From it may be traced the lower third or half of the external surface of the shaft of the bone in the interval between the Peroneus tertius in front and the other two Peronei tendons behind.

Surgical Anatomy.—In fractures of the bones of the leg both bones are usually fractured, but each bone may be broken separately, the fibula more frequently than the tibia. Fracture of both bones may be caused either by direct or indirect violence. When it occurs from indirect force, the fracture in the tibia is at the junction of the middle and lower third of the bone. Many causes conduce to render this the weakest part of the bone. The fracture of the fibula is usually at rather a higher level. These fractures present great variety, both as regards their direction and condition. They may be oblique, transverse, longitudinal, or spiral. When oblique, they are usually the result of indirect violence, and the direction of the fracture is from behind, downward, forward, and inward in many cases, but may be downward and outward or downward and backward. When transverse, the fracture is often at the upper part of the bone, and is the result of direct violence. The spiral fracture usually commences as a vertical fissure, involving the ankle-joint, and is associated with fracture of the fibula higher up. It is the result of torsion, from twisting of the body whilst the foot is fixed.

Fractures of the tibia alone are almost always the result of direct violence, except where the malleolus is broken off by twists of the foot. Fractures of the fibula alone may arise from indirect or direct force, those of the lower end being usually the result of the former, and those higher up being caused by a direct blow on the part.

The tibia and fibula, like the femur, are frequently the seat of acute necrosis. Chronic abscess is more frequently met with in the cancellous tissue of the head and lower end of the tibia than in any other bone of the body. The abscess is of small size, very chronic, and probably the result of tuberculous osteitis in the highly vascular growing tissue at the end of the shaft near the epiphyseal cartilage in the young subject.

The tibia is the bone which is most frequently and most extensively distorted in rickets. It gives way at the junction of the middle and lower third, its weakest part, and presents a curve forward and outward.

THE FOOT (Figs. 137, 138).

The skeleton of the Foot consists of three divisions: the Tarsus, Metatarsus, and Phalanges.

The Tarsus.

The bones of the Tarsus are seven in number: viz., the calcaneum or os calcis, astragalus, cuboid, navicular, internal, middle, and external cuneiform bones.

The Calcaneum (Fig. 139).

The **Calcaneum**, or **Os Calcis** (*calx*, the heel), is the largest and strongest of the tarsal bones. It is irregularly cuboidal in form, having its long axis directed forward and outward. It is situated at the lower and back part of the foot, serving to transmit the weight of the body to the ground, and forming a strong lever for the muscles of the calf. It presents for examination six surfaces: superior, inferior, external, internal, anterior, and posterior.

The **superior surface** is formed behind by the upper aspect of that part of the os calcis which projects backward to form the heel. It varies in length in different individuals; is convex from side to side, concave from before backward, and corresponds above to a mass of adipose substance placed in front of the tendo Achillis. In the middle of the superior surface are two (sometimes three) articular facets, separated by a broad shallow groove, which is directed obliquely forward and outward, and is rough for the attachment of the interosseous ligament connecting the astragalus and os calcis. Of the two articular surfaces, the *external* is the larger, and situated on the body of the bone: it is of an oblong form, wider behind than in front, and convex from before backward. The *internal articular surface* is supported on a projecting process of bone, called the *lesser process* of the calcaneum (*sustentaculum tali*); it is also oblong, concave longitudinally, and sometimes subdivided into two parts, which differ in size and shape. More anteriorly is seen the upper surface of the *greater process*, marked by a rough depression for the attachment of numerous ligaments, and a tubercle for the origin of the Extensor brevis digitorum muscle.

The **inferior surface** is narrow, rough, uneven, wider behind than in front and convex from side to side; it is bounded posteriorly by two tubercles separated by a rough depression; the *external*, small, prominent, and rounded, gives attachment to part of the Abductor minimi digiti: the *internal*, broader and larger, for the support of the heel, gives attachment, by its prominent inner margin, to the Abductor hallucis, and in front to the Flexor brevis digitorum muscles and plantar fascia; the depression between the tubercles gives attachment to the Abductor minimi digiti. The rough surface in front of the tubercles gives attachment to the long plantar ligament and to the outer head of the Flexor accessorius muscle; while a prominent tubercle nearer the anterior part of this surface, as well as to a transverse groove in front of it, is attached the short plantar ligament.

The **external surface** is broad, flat, and almost subcutaneous; it presents near its centre a tubercle, for the attachment of the middle fasciculus of the external lateral ligament. At its upper and anterior part this surface gives attachment to

FIG. 137.—Bones of the right foot. Dorsal surface.

the external calcaneo-astragaloid ligament; and in front of the tubercle it presents a narrow surface marked by two oblique grooves, separated by an elevated ridge which varies much in size in different bones; it is named the *peroneal tubercle*, and gives attachment to a fibrous process from the external annular ligament. The *superior groove* transmits the tendon of the *Peroneus brevis*; the *inferior*, the tendon of the *Peroneus longus*.

The **internal surface** is deeply concave; it is directed obliquely downward and forward, and serves for the transmission of the plantar vessels and nerves into the sole of the foot; it affords attachment to part of the *Flexor accessorius* muscle. At its upper and fore part it presents an eminence of bone, the *lesser process* or *sustentaculum tali*, which projects horizontally inward, and to it a slip of the tendon of the *Tibialis posticus* is attached. This process is concave above, and supports the

FIG. 139.—The left os calcis. A. Postero-external view. B. Antero-internal view.

anterior articular surface of the astragalus; below, it is grooved for the tendon of the *Flexor longus hallucis*. Its free margin is rough, for the attachment of part of the internal lateral ligament of the ankle-joint.

The **anterior surface**, of a somewhat triangular form, articulates with the cuboid. It is concave from above downward and outward, and convex in the opposite direction. Its inner border gives attachment to the inferior calcaneo-navicular ligament.

The **posterior surface** is rough, prominent, convex, and wider below than above. Its lower part is rough, for the attachment of the tendo Achillis and the tendon of the *Plantaris* muscle; its upper part is smooth, and is covered by a bursa which separates the tendons from the bone.

Articulations.—With two bones: the astragalus and cuboid.

Attachment of Muscles.—To eight: part of the *Tibialis posticus*, the tendo

Achillis, Plantaris, Abductor hallucis, Abductor minimi digiti, Flexor brevis digitorum, Flexor accessorius, and Extensor brevis digitorum.

The Astragalus (Fig. 140).

The **Astragalus** (ἀστράγαλος, a die) is the largest of the tarsal bones, next to

FIG. 140 —The left astragalus. A. Superior and external view. B. Inferior and internal view.

the os calcis. It occupies the middle and upper part of the tarsus, supporting the tibia above, articulating with the malleoli on either side, resting below upon the os calcis, and joined in front to the navicular. This bone may easily be recognized by its large rounded head, by the broad articular facet on its upper convex surface, or by the two articular facets separated by a deep groove on its under concave surface. It presents six surfaces for examination.

The **superior surface** presents, behind, a broad smooth trochlear surface for articulation with the tibia. The trochlea is broader in front than behind, convex from before backward, slightly concave from side to side; in front of it is the upper surface of the neck of the astragalus, rough for the attachment of ligaments. The **inferior surface** presents two articular facets separated by a deep groove. The groove runs obliquely forward and outward, becoming gradually broader and deeper in front: it corresponds with a similar groove upon the upper surface of the os calcis, and forms, when articulated with that bone, a canal, filled up in the recent state by the interosseous calcaneo-astragaloid ligament. Of the two articular facets, the posterior is the larger, of an oblong form and deeply concave from side to side; the anterior is shorter and narrower, of an elongated oval form, convex longitudinally, and often subdivided into two by an elevated ridge; of these, the posterior articulates with the lesser process of the os calcis; the anterior, with the upper surface of the inferior calcaneo-navicular ligament. The **internal surface** presents at its upper part a pear-shaped articular facet for the inner malleolus, continuous above with the trochlear surface; below the articular surface is a rough depression, for the attachment of the deep portion of the internal lateral ligament. The **external surface** presents a large triangular facet, concave from above downward for articulation with the external malleolus; it is continuous above with the trochlear surface; and in front of it is a rough depression for the attachment of the anterior fasciculus of the external lateral ligament of the ankle-joint. The **anterior surface**, convex and rounded, forms the *head* of the astragalus; it is smooth, of an oval form, and directed obliquely inward and downward; it articulates with the navicular. On its under and inner surface is a small facet, continuous in front with the articular surface of the head, and behind with the smaller facet for the os calcis. This rests on the inferior calcaneo-navicular ligament, being separated from it by the synovial membrane, which is prolonged from the anterior calcaneo-astragaloid joint to the astragalo-navicular joint. The head is surrounded

by a constricted portion, the *neck* of the astragalus. The *posterior surface* is narrow, and traversed by a groove, which runs obliquely downward and inward, and transmits the tendon of the Flexor longus hallucis, external to which is a prominent tubercle, to which the posterior fasciculus of the external lateral ligament is attached. This tubercle is sometimes separated from the rest of the astragalus, and is then known as the *os trigonum*. To the inner side of the groove is a second, but less marked, tubercle.

To ascertain to which foot the bone belongs, hold it with the broad articular surface upward, and the rounded head forward; the lateral triangular articular surface for the external malleolus will then point to the side to which the bone belongs.

Articulations.—With four bones: tibia, fibula, os calcis, and navicular.

The Cuboid (Fig. 141).

The **Cuboid** (κύβος, a cube; εἶδος, like) bone is placed on the outer side of the foot, in front of the os calcis, and behind the fourth and fifth metatarsal bones. It

FIG. 141.—The left cuboid. A. Antero-internal view. B. Postero-external view.

is of a pyramidal shape, its base being directed inward, its apex outward. It may be distinguished from the other tarsal bones by the existence of a deep groove on its under surface, for the tendon of the Peroneus longus muscle. It presents for examination six surfaces: three articular and three non-articular.

The **non-articular surfaces** are the superior, inferior, and external. The *superior* or *dorsal surface*, directed upward and outward, is rough, for the attachment of numerous ligaments. The *inferior* or *plantar surface* presents in front a deep groove, which runs obliquely from without, forward and inward; it lodges the tendon of the Peroneus longus, and is bounded behind by a prominent ridge, to which is attached the long calcaneo-cuboid ligament. The ridge terminates externally in an eminence, the *tuberosity of the cuboid*, the surface of which presents a convex facet, for articulation with the sesamoid bone of the tendon contained in the groove. The surface of bone behind the groove is rough, for the attachment of the short plantar ligament, a few fibres of the Flexor brevis hallucis, and a fasciculus from the tendon of the Tibialis posticus. The *external surface*, the smallest and narrowest of the three, presents a deep notch formed by the commencement of the peroneal groove.

The **articular surfaces** are the posterior, anterior, and internal. The *posterior surface* is smooth, triangular, and concavo-convex, for articulation with the anterior surface of the os calcis. The *anterior*, of smaller size, but also irregularly triangular, is divided by a vertical ridge into two facets: the inner one, quadrilateral in form, articulates with the fourth metatarsal bone; the outer one, larger and more triangular, articulates with the fifth metatarsal. The *internal surface* is broad, rough, irregularly quadrilateral, presenting at its middle and upper part a smooth oval facet, for articulation with the external cuneiform bone; and behind this (occasionally) a smaller facet, for articulation with the navicular; it is rough in the rest of its extent, for the attachment of strong interosseous ligaments.

To ascertain to which foot the bone belongs, hold it so that its under surface, marked by the peroneal groove, looks downward, and the large concavo-convex articular surface backward toward the holder: the narrow non-articular surface, marked by the commencement of the peroneal groove, will point to the side to which the bone belongs.

Articulations.—With four bones: the os calcis, external cuneiform, and the fourth and fifth metatarsal bones; occasionally with the navicular.

Attachment of Muscles.—Part of the Flexor brevis hallucis and a slip from the tendon of the Tibialis posticus.

The Navicular (Fig. 142).

The Navicular or Scaphoid bone is situated at the inner side of the tarsus,

FIG. 142.—The left navicular. A. Antero-external view. B. Postero-internal view.

between the astragalus behind and the three cuneiform bones in front. It may be distinguished by its form, being concave behind, convex and subdivided into three facets in front.

The *anterior surface*, of an oblong form, is convex from side to side, and subdivided by two ridges into three facets, for articulation with the three cuneiform bones. The *posterior surface* is oval, concave, broader externally than internally, and articulates with the rounded head of the astragalus. The *superior surface* is convex from side to side, and rough for the attachment of ligaments. The *inferior* is irregular, and also rough for the attachment of ligaments. The *internal surface* presents a rounded tubercular eminence, the *tuberosity* of the navicular, the lower part of which projects, and gives attachment to part of the tendon of the Tibialis posticus. The *external surface* is rough and irregular, for the attachment of ligamentous fibres, and occasionally presents a small facet for articulation with the cuboid bone.

To ascertain to which foot the bone belongs, hold it with the concave articular surface backward, and the convex dorsal surface upward; the external surface—*i. e.* the surface opposite the tubercle—will point to the side to which the bone belongs.

Articulations.—With four bones: astragalus and three cuneiform; occasionally also with the cuboid.

Attachment of Muscles.—Part of the Tibialis posticus.

The Cuneiform Bones.

The Cuneiform Bones have received their name from their wedge-like shape (*cuneus*, a wedge; *forma*, likeness). They form, with the cuboid, the anterior row of the tarsus, being placed between the navicular behind, the three innermost metatarsal bones in front, and the cuboid externally. They are called the *first*, *second*, and *third*, counting from the inner to the outer side of the foot, and, from their position, *internal*, *middle*, and *external*.

THE INTERNAL CUNEIFORM (Fig. 143).

The **Internal Cuneiform** is the largest of the three. It is situated at the inner side of the foot, between the navicular behind and the base of the first metatarsal in front. It may be distinguished from the other two by its large size, and by its not presenting such a distinct wedge-like form. Without the others it may be known by the large, kidney-shaped anterior articulating surface and by the prominence on the inferior or plantar surface for the attachment of the *Tibialis posticus*. It presents for examination six surfaces.

FIG. 143.—The left internal cuneiform. A. Antero-internal view. B. Postero-external view.

The *internal surface* is subcutaneous, and forms part of the inner border of the foot; it is broad, quadrilateral, and presents at its anterior inferior angle a smooth oval facet, into which the tendon of the *Tibialis anticus* is partially inserted; in the rest of its extent it is rough, for the attachment of ligaments. The *external surface* is concave, presenting, along its superior and posterior borders, a narrow reversed L-shaped surface for articulation with the middle cuneiform behind, and second metatarsal bone in front; in the rest of its extent it is rough for the attachment of ligaments and part of the tendon of the *Peroneus longus*. The *anterior surface*, kidney-shaped, much larger than the posterior, articulates with the metatarsal bone of the great toe. The *posterior surface* is triangular, concave, and articulates with the innermost and largest of the three facets on the anterior surface of the navicular. The *inferior* or *plantar surface* is rough, and presents a prominent tuberosity at its back part for the attachment of part of the tendon of the *Tibialis posticus*. It also gives attachment in front to part of the tendon of the *Tibialis anticus*. The *superior surface* is the narrow-pointed end of the wedge, which is directed upward and outward; it is rough for the attachment of ligaments.

To ascertain to which side the bone belongs, hold it so that its superior narrow edge looks upward, and the long, kidney-shaped, articular surface forward; the external surface, marked by its vertical and horizontal articular facets, will point to the side to which it belongs.

Articulations.—With four bones: navicular, middle cuneiform, first and second metatarsal bones.

Attachment of Muscles.—To three: the *Tibialis anticus* and *posticus*, and *Peroneus longus*.

THE MIDDLE CUNEIFORM (Fig. 144).

The **Middle Cuneiform**, the smallest of the three, is of very regular wedge-like form, the broad extremity being placed upward, the narrow end downward. It is situated between the other two bones of the same name, and articulates with the navicular behind and the second metatarsal in front. It is smaller than the external cuneiform bone, from which it may be further distinguished by the L-shaped articular facet, which runs round the upper and back part of its inner surface.

FIG. 144.—The left middle cuneiform. A. Antero-internal view. B. Postero-external view.

The *anterior surface*, triangular in form and narrower than the posterior, articulates with the base of the second metatarsal bone. The *posterior surface*, also triangular, articulates with the navicular.

The *internal surface* presents a reversed L-shaped articular facet, running along the superior and posterior borders, for articulation with the internal cuneiform, and is rough in the rest of its extent for the attachment of ligaments. The *external surface* presents posteriorly a smooth facet for articulation with the external cuneiform bone. The *superior surface* forms the base of the wedge; it is quadrilateral, broader behind than in front, and rough for the attachment of ligaments. The *inferior surface*, pointed and tubercular, is also rough for ligamentous attachment and for the insertion of a slip from the tendon of the Tibialis posticus.

To ascertain to which foot the bone belongs, hold its superior or dorsal surface upward, the broadest edge being toward the holder: the smooth facet (limited to the posterior border) will then point to the side to which it belongs.

Articulations.—With four bones: navicular, internal and external cuneiform, and second metatarsal bone.

Attachment of Muscles.—A slip from the tendon of the Tibialis posticus is attached to this bone.

THE EXTERNAL CUNEIFORM (Fig. 145).

The **External Cuneiform**, intermediate in size between the two preceding, is of a very regular wedge-like form, the broad extremity being placed upward, the narrow end downward. It occupies the centre of the front row of the tarsus, between the middle cuneiform internally, the cuboid externally, the navicular behind, and the third metatarsal in front. It is distinguished from the internal cuneiform bone by its more regular wedge-like shape and by the absence of the kidney-shaped articular surface: from the middle cuneiform, by the absence of the reversed L-shaped facet, and by the two articular facets which are present on both its inner and outer surfaces. It has six surfaces for examination.

FIG. 145.—The left external cuneiform. A. Postero-internal view. B. Antero-external view.

The *anterior surface*, triangular in form, articulates with the third metatarsal bone. The *posterior surface* articulates with the most external facet of the navicular, and is rough below for the attachment of ligamentous fibres. The *internal surface* presents two articular facets, separated by a rough depression; the anterior one, sometimes divided into two, articulates with the outer side of the base of the second metatarsal bone; the posterior one skirts the posterior border and articulates with the middle cuneiform; the rough depression between the two gives attachment to an interosseous ligament. The *external surface* also presents two articular facets, separated by a rough non-articular surface; the anterior facet, situated at the superior angle of the bone, is small, and articulates with the inner side of the base of the fourth metatarsal; the posterior and larger one articulates with the cuboid; the rough, non-articular surface serves for the attachment of an interosseous ligament. The three facets for articulation with the three metatarsal bones are continuous with one another, and covered by a prolongation of the same cartilage; the facets for articulation with the middle cuneiform and navicular are also continuous, but that for articulation with the cuboid is usually separate. The *superior* or *dorsal surface* is of an oblong square form, its posterior external angle being prolonged backward. The *inferior* or *plantar surface* is an obtuse rounded margin, and serves for the attachment of part of the tendon of the Tibialis posticus, part of the Flexor brevis hallucis, and ligaments.

To ascertain to which side the bone belongs, hold it with the broad dorsal

surface upward, the prolonged edge backward; the separate articular facet for the cuboid will point to the proper side.

Articulations.—With six bones: the navicular, middle cuneiform, cuboid, and second, third, and fourth metatarsal bones.

Attachment of Muscles.—To two: part of the *Tibialis posticus*, and *Flexor brevis hallucis*.

The number of tarsal bones may be reduced owing to congenital ankylosis, which may occur between the os calcis and cuboid, the os calcis and navicular, the os calcis and astragalus, or the astragalus and navicular.

The Metatarsal Bones.

The **Metatarsal Bones** are five in number, and are numbered one to five, in accordance with their position from within outward; they are long bones, and present for examination a shaft and two extremities.

Common Characters.—The *shaft* is prismoid in form, tapers gradually from the tarsal to the phalangeal extremity, and is slightly curved longitudinally, so as to be concave below, slightly convex above. The *posterior extremity*, or *base*, is wedge-shaped, articulating by its terminal surface with the tarsal bones, and by its lateral surfaces with the contiguous metatarsal bones, its dorsal and plantar surfaces being rough for the attachment of ligaments. The *anterior extremity*, or *head*, presents a terminal rounded articular surface, oblong from above downward, and extending farther backward below than above. Its sides are flattened and present a depression, surmounted by a tubercle, for ligamentous attachment. Its under surface is grooved in the middle line for the passage of the *Flexor* tendon, and marked on each side by an articular eminence continuous with the terminal articular surface.

Peculiar Characters.—The **First** (Fig. 146) is remarkable for its great thickness, but is the shortest of all the metatarsal bones. The *shaft* is strong and of well-marked prismoid form. The *posterior extremity* presents, as a rule, no lateral articular facet, but occasionally on the outer side there is an oval facet by which it articulates with the second metatarsal bones. Its terminal articular surface is of large size, kidney-shaped; its circumference is grooved, for the tarso-metatarsal ligaments, and internally gives attachment to part of the tendon of the *Tibialis anticus*: its inferior angle presents a rough oval prominence for the insertion of the tendon of the *Peroneus longus*. The *head* is of large size;

FIG. 146.—The first metatarsal. (Left.)

on its plantar surface are two grooved facets, over which glide sesamoid bones; the facets are separated by a smooth elevated ridge.

This bone is known by the single kidney-shaped articular surface on its base, the deeply grooved appearance of the plantar surface of its head, and its great thickness relatively to its length. When it is placed in its natural position, the concave border of the kidney-shaped articular surface on its base points to the side to which the bone belongs.

Attachment of Muscles.—To three: part of the *Tibialis anticus*, the *Peroneus longus*, and the *First dorsal interosseous*.

The **Second** (Fig. 147) is the longest and largest of the remaining metatarsal bones, being prolonged backward into the recess formed between the three cuneiform bones. Its *tarsal extremity* is broad above, narrow and rough below. It presents four articular surfaces: one behind, of a triangular form, for articulation with the middle cuneiform; one at the upper part of its internal lateral surface, for articulation with the internal cuneiform; and two on its external lateral surface—an upper and a lower, separated by a rough non-articular interval. Each of these articular surfaces is divided by a vertical ridge into two facets, thus making four facets; the two anterior of these articulate with the third metatarsal; the two posterior (sometimes continuous) with the external cuneiform. In addition

FIG. 147.—The second metatarsal. (Left.)

FIG. 148.—The third metatarsal. (Left.)

to these articular surfaces there is occasionally a fifth when this bone articulates with the first metatarsal bone. It is oval in shape, and is situated on the inner side of the shaft near the base.

The facets on the tarsal extremity of the second metatarsal bone serve at once to distinguish it from the rest, and to indicate the foot to which it belongs; there being one facet at the upper angle of the internal surface, and two facets, each subdivided into two parts, on the external surface, pointing to the side to which the bone belongs. The fact that the two posterior subdivisions of these external facets sometimes run into one should not be forgotten.

Attachment of Muscles.—To four: the Adductor obliquus hallucis, First and Second dorsal interosseous, and a slip from the tendon of the Tibialis posticus; occasionally also a slip from the Peroneus longus.

The **Third** (Fig. 148) articulates behind, by means of a triangular smooth surface, with the external cuneiform; on its inner side, by two facets, with the second metatarsal; and on its outer side, by a single facet, with the fourth metatarsal. The latter facet is of circular form and situated at the upper angle of the base.

The third metatarsal is known by its having at its tarsal end two undivided facets on the inner side, and a single facet on the outer. This distinguishes it from the second metatarsal, in which the two facets, found on one side of its tarsal end, are each subdivided into two. The single facet (when the bone is put in its natural position) is on the side to which the bone belongs.

Attachment of Muscles.—To five: Adductor obliquus hallucis, Second and Third dorsal, and First plantar interosseous, and a slip from the tendon of the Tibialis posticus.

The **Fourth** (Fig. 149) is smaller in size than the preceding; its *tarsal extremity* presents a terminal quadrilateral surface, for articulation with the cuboid; a smooth facet on the inner side, divided by a ridge into an anterior portion for articulation with the third metatarsal, and a posterior portion for articulation with the external cuneiform; on the outer side a single facet, for articulation with the fifth metatarsal.

The fourth metatarsal is known by its having a single facet on either side of the tarsal extremity, that on the inner side being divided into two parts. If this subdivision be not recognizable, the fact that its tarsal end is bent somewhat outward will indicate the side to which it belongs.

Attachment of Muscles.—To five: Adductor obliquus hallucis, Third and Fourth dorsal, and Second plantar interosseous, and a slip from the tendon of the Tibialis posticus.

FIG. 149.—The fourth metatarsal. (Left.)

FIG. 150.—The fifth metatarsal. (Left.)

The **Fifth** (Fig. 150) is recognized by the tubercular eminence on the outer side of its base. It articulates behind, by a triangular surface cut obliquely from without inward, with the cuboid, and internally with the fourth metatarsal.

The projection on the outer side of this bone at its tarsal end at once distinguishes it from the others, and points to the side to which it belongs.

Attachment of Muscles.—To six: the Peroneus brevis, Peroneus tertius, Flexor brevis minimi digiti, Adductor transversus hallucis, Fourth dorsal, and Third plantar.

Articulations.—Each bone articulates with the tarsal bones by one extremity, and by the other with the first row of phalanges. The number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth.

The Phalanges.

The **Phalanges** of the foot, both in number and general arrangement, resemble those in the hand; there being two in the great toe and three in each of the other toes.

The phalanges of the *first row* resemble closely those of the hand. The *shaft* is compressed from side to side, convex above, concave below. The *posterior extremity* is concave; and the *anterior extremity* presents a trochlear surface, for articulation with the second phalanges.

The phalanges of the *second row* are remarkably small and short, but rather broader than those of the first row.

The *ungual* phalanges in form resemble those of the fingers; but they are smaller, flattened from above downward, presenting a broad base for articulation with the second row, and an expanded extremity for the support of the nail and end of the toe.

Articulation.—The first row, with the metatarsal bones behind and second phalanges in front; the second row of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row of the four outer toes, with the second phalanges.

Attachment of Muscles.—To the first phalanges. Great toe, five muscles: innermost tendon of Extensor brevis digitorum, Abductor hallucis, Adductor obliquus hallucis, Flexor brevis hallucis, Adductor transversus hallucis. Second toe, three muscles: First and Second dorsal interosseous and First lumbrical. Third toe, three muscles: Third dorsal and First plantar interosseous and Second lumbrical. Fourth toe, three muscles: Fourth dorsal and Second plantar interosseous and Third lumbrical. Fifth toe, four muscles: Flexor brevis minimi digiti, Abductor minimi digiti, and Third plantar interosseous, and Fourth lumbrical.—Second phalanges. Great toe; Extensor longus hallucis, Flexor longus hallucis. Other toes; Flexor brevis digitorum, one slip of the common tendon of the Extensor longus and brevis digitorum.¹—Third phalanges: two slips from the common tendon of the Extensor longus and Extensor brevis digitorum, and the Flexor longus digitorum.

Development of the Foot (Fig. 151)

The **Tarsal bones** are each developed by a single centre, excepting the os calcis, which has an epiphysis for its posterior extremity. The centres make their appearance in the following order: os calcis, at the sixth month of foetal life; astragalus, about the seventh month; cuboid, at the ninth month; external cuneiform, during the first year; internal cuneiform in the third year; middle cuneiform and navicular in the fourth year. The epiphysis for the posterior tuberosity of the os calcis appears at the tenth year, and unites with the rest of the bone soon after puberty.

The **Metatarsal bones** are each developed by *two* centres: one for the shaft and one for the digital extremity in the four outer metatarsal; one for the shaft and one for the base in the metatarsal bone of the great toe.² Ossification commences in the centre of the shaft about the ninth week, and extends toward either extremity. The centre in the proximal end of the first metatarsal bone appears about the third year, the centre in the distal end of the other bones between the fifth and eighth years; they become joined between the eighteenth and twentieth years.

The **Phalanges** are developed by *two* centres for each bone: one for the shaft and one for the metatarsal extremity. The centre for the shaft appears about the tenth week, that for the epiphysis between the fourth and tenth years; they join the shaft about the eighteenth year.

Construction of the Foot as a Whole.

The foot is constructed on the same principles as the hand, but modified to form a firm basis of support for the rest of the body when in the erect position. It

¹ Except the second phalanx of the fifth toe, which receives no slip from the Extensor brevis digitorum.

² As was noted in the first metacarpal bone, so in the first metatarsal, there is often to be observed a tendency to the formation of a second epiphysis in the distal extremity. (See footnote, p. 171.)

is more solidly constructed, and its component parts are less movable on each other than in the hand. This is especially the case with the great toe, which has to assist in supporting the body, and is therefore constructed with greater solidity; it lies parallel with the other toes, and has a very limited degree of mobility, whereas the thumb, which is occupied in numerous and varied movements, is constructed in such a manner as to permit of great mobility. Its metacarpal bone is directed away from the others, so as to form an acute angle with the second, and it enjoys a considerable range of motion at its articulation with the carpus. The foot is placed at right angles to the leg—a position which is almost peculiar to man, and has relation to the erect position which he maintains. In order to allow of its supporting the weight of the whole body in this position with the least expenditure of material, it is constructed in the form of an arch. This arch is not, however, made up of two equal limbs. The hinder one, which is made up of the os calcis and the posterior part of the astragalus, is about half the length of the anterior limb, and measures about three inches. The anterior limb consists of the rest of

the heads of the metatarsal bones anteriorly. The weakest part of the arch is the joint between the astragalus and scaphoid, and here it is more liable to yield in those who are overweighted, and in those in whom the ligaments which complete and preserve the arch are relaxed. This weak point in the arch is braced on its concave surface by the inferior calcaneo-navicular ligament, which is more elastic than most other ligaments, and thus allows the arch to yield from jars or shocks applied to the anterior portion of the foot and quickly restores it to its pristine condition. This ligament is supported internally by blending with the Deltoid ligament, and inferiorly by the tendon of the *Tibialis posticus* muscle, which is spread out into a fan-shaped insertion, and prevents undue tension of the ligament or such an amount of stretching as would permanently elongate it.

In addition to this longitudinal arch the foot presents a transverse arch, at the anterior part of the tarsus and hinder part of the metatarsus. This, however, can scarcely be described as a true arch, but presents more the character of a half-dome. The inner border of the central portion of the longitudinal arch is elevated from the ground, and from this point the bones arch over to the outer border, which is in contact with the ground, and, assisted by the longitudinal arch, produce a sort of rounded niche on the inner side of the foot, which gives the appearance of a transverse as well as a longitudinal arch.

The line of the foot, from the point of the heel to the toes, is not quite straight, but is directed a little outward, so that the inner border is a little convex and the outer border concave. This disposition of the bones becomes more marked when the longitudinal arch of the foot is lost, as in the disease known under the name of "flat-foot."

Surface Form.—On the dorsum of the foot the individual bones are not to be distinguished with the exception of the head of the astragalus, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole surface forms a smooth convex outline, the summit of which is the ridge formed by the head of the astragalus, the navicular, the middle cuneiform, and the second metatarsal bones; from this it gradually inclines outward and more rapidly inward. On the inner side of the foot, the internal tuberosity of the *os calcis* and the ridge separating the inner from the posterior surface of the bone may be felt most posteriorly. In front of this, and below the internal malleolus, may be felt the projection of the *sustentaculum tali*. Passing forward is the well-marked tuberosity of the navicular bone, situated about an inch or an inch and a quarter in front of the internal malleolus. Further toward the front, the ridge formed by the base of the first metatarsal bone can be obscurely felt, and from this the shaft of the bone can be traced to the expanded head articulating with the base of the first phalanx of the great toe. Immediately beneath the base of this phalanx, the internal sesamoid bone is to be felt. Lastly, the expanded ends of the bones forming the last joint of the great toe are to be felt. On the outer side of the foot the most posterior bony point is the outer tuberosity of the *os calcis*, with the ridge separating the posterior from the outer surface of the bone. In front of this the greater part of the external surface of the *os calcis* is subcutaneous; on it, below and in front of the external malleolus, may be felt the peroneal ridge, when this process is present. Farther forward, the base of the fifth metatarsal bone forms a prominent and well-defined landmark, and in front of this the shaft of the bone, with its expanded head, and the base of the first phalanx may be defined. The sole of the foot is almost entirely covered by soft parts, so that but few bony parts are to be made out, and these somewhat obscurely. The hinder part of the under surface of the *os calcis* and the heads of the metatarsal bones, with the exception of the first, which is concealed by the sesamoid bones, may be recognized.

Surgical Anatomy.—Considering the injuries to which the foot is subjected, it is surprising how seldom the tarsal bones are fractured. This is no doubt due to the fact that the tarsus is composed of a number of bones, articulated by a considerable extent of surface and joined together by very strong ligaments, which serve to break the force of violence applied to this part of the body. When fracture does occur, these bones, being composed for the most part of a soft cancellous structure, covered only by a thin shell of compact tissue, are often extensively comminuted, especially as most of the fractures are produced by direct violence. And having only a very scanty amount of soft parts over them, the fractures are very often compound, and amputation is frequently necessary.

When fracture occurs in the anterior group of tarsal bones, it is almost invariably the result of direct violence; but fractures of the posterior group, that is, of the calcaneum and astragalus, are most frequently produced by falls from a height on to the feet; though fracture of the *os calcis* may be caused by direct violence or by muscular action. The posterior part of the bone, that is, the part behind the articular surfaces, is almost always the seat of the fracture, though some few cases of fracture of the *sustentaculum tali* and of vertical fracture between the two articulating facets have been recorded. The neck of the astragalus, being the weakest

part of the bone, is most frequently fractured, though fractures may occur in any part and almost in any direction, either associated or not with fracture of other bones.

In cases of club-foot, especially in congenital cases, the bones of the tarsus become altered in shape and size, and displaced from their proper positions. This is especially the case in congenital equino-varus, in which the astragalus, particularly about the head, becomes twisted and atrophied, and a similar condition may be present in the other bones, more especially the navicular. The tarsal bones are peculiarly liable to become the seat of tuberculous caries from comparatively trivial injuries. There are several reasons to account for this. They are composed of a delicate cancellated structure, surrounded by intricate synovial membranes. They are situated at the farthest point from the central organ of the circulation and exposed to vicissitudes of temperature; and, moreover, on their dorsal surface are thinly clad with soft parts which have but a scanty blood-supply. And finally, after slight injuries, they are not maintained in a condition of rest to the same extent as similar injuries in some other parts of the body. Caries of the calcaneum or astragalus may remain limited to the one bone for a long period, but when one of the other bones is affected, the remainder frequently become involved, in consequence of the disease spreading through the large and complicated synovial membrane which is more or less common to these bones.

Amputation of the whole or a part of the foot is frequently required either for injury or disease. The principal amputations are as follow: (1) Syme's: amputation at the ankle-joint by a heel-flap, with removal of the malleoli and sometimes a thin slice from the lower end of the tibia. (2) Roux's: amputation at the ankle-joint by a large internal flap. (3) Pirogoff's amputation: removal of the whole of the tarsal bones, except the posterior part of the os calcis and a thin slice from the tibia and fibula including the two malleoli. The sawn surface of the os calcis is then turned up and united to the similar surface of the tibia. (4) Subastragaloid amputation: removal of the foot below the astragalus through the joint between it and the os calcis. This operation has been modified by Hancock, who leaves the posterior third of the os calcis and turns it up against the denuded surface of the astragalus. This latter operation is of doubtful utility and is rarely performed. (5) Chopart's or medio-tarsal: removal of the anterior part of the foot with all the tarsal bones except the os calcis and astragalus; disarticulation being effected through the joints between the astragalo-scaphoid and calcaneo-cuboid in joints. (6) Lisfranc's: amputation of the anterior part of the foot through the tarso-metatarsal joints. This has been modified by Hey, who disarticulated through the joints of the four outer metatarsal bones with the tarsus, and sawed off the projecting internal cuneiform; and by Skey, who sawed off the base of the second metatarsal bone and disarticulated the others.

The bones of the tarsus occasionally require removal individually. This is especially the case with the astragalus and os calcis for disease limited to the one bone, or again the astragalus may require excision in cases of subastragaloid dislocation, or, as recommended by Mr. Lund, in cases of inveterate talipes. The cuboid has been removed for the same reason by Mr. Solly. But both these two latter operations have fallen very much into disuse, and have been superseded by resection of a wedge-shaped piece of bone from the outer side of the tarsus. Finally, Mickulicz and Watson have devised operations for the removal of more extensive portions of the tarsus. Mickulicz's operation consists in the removal of the os calcis and astragalus, along with the articular surfaces of the tibia and fibula, and also of the scaphoid and cuboid. The remaining portion of the tarsus is then brought into contact with the sawn surfaces of the tibia and fibula, and fixed there. The result is a position of the shortened foot resembling talipes equinus. Watson's operation is adapted to those cases where the disease is confined to the anterior tarsal bones. By two lateral incisions he saws through the bases of the metatarsal bones in front and opens up the joints between the scaphoid and astragalus, and the cuboid and os calcis, and removes the intervening bones.

The metatarsal bones and phalanges are nearly always broken by direct violence, and in the majority of cases the injury is the result of severe crushing accidents, necessitating amputation. The metatarsal bones, and especially that of the great toe, are frequently diseased, either in tubercular subjects or in perforating ulcer of the foot.

Sesamoid Bones.

These are small rounded masses, cartilaginous in early life, osseous in the adult, which are developed in those tendons which exert a great amount of pressure upon the parts over which they glide. It is said that they are more commonly found in the male than in the female, and in persons of an active muscular habit than in those who are weak and debilitated. They are invested throughout their whole surface by the fibrous tissue of the tendon in which they are found, excepting upon that side which lies in contact with the part over which they play, where they present a free articular facet. They may be divided into two kinds: those which glide over the articular surfaces of joints, and those which play over the cartilaginous facets found on the surfaces of certain bones.

The sesamoid bones of the joints in the upper extremity, are two on the palmar surface of the metacarpo-phalangeal joint in the thumb, developed in the tendons of the *Flexor brevis pollicis*; occasionally one or two opposite the metacarpo-phalangeal articulations of the fore and little fingers; and, still more rarely, one opposite the same joints of the third and fourth fingers. In the lower extremity, the patella, which is developed in the tendon of the *Quadriceps extensor*; two small sesamoid bones, found in the tendons of the *Flexor brevis hallucis*, opposite the metatarso-phalangeal joint of the great toe; and occasionally one in the metatarso-phalangeal joint of the second toe, the little toe, and, still more rarely, the third and fourth toes.

Those found in the tendons which glide over certain bones occupy the following situations: one sometimes found in the tendon of the *Biceps cubiti*, opposite the tuberosity of the radius: one in the tendon of the *Peroneus longus*, where it glides through the groove in the cuboid bone; one appears late in life in the tendon of the *Tibialis anticus*, opposite the smooth facet of the internal cuneiform bone; one is found in the tendon of the *Tibialis posticus*, opposite the inner side of the head of the astragalus; one in the outer head of the *Gastrocnemius*, behind the outer condyle of the femur; and one in the conjoined tendon of the *Psoas* and *Iliacus*, where it glides over the *os pubis*. Sesamoid bones are found occasionally in the tendon of the *Gluteus maximus*, as it passes over the great trochanter, and in the tendons which wind round the inner and outer malleoli.

THE ARTICULATIONS.

THE various bones of which the Skeleton consists are connected together at different parts of their surfaces, and such a connection is designated by the name of *Joint* or *Articulation*. If the joint is *immovable*, as between the cranial and most of the facial bones, the adjacent margins of the bones are applied in almost close contact, a thin layer of fibrous membrane, the *sutural ligament*, and, at the base of the skull, in certain situations, a thin layer of cartilage, being interposed. Where slight movement is required, combined with great strength, the osseous surfaces are united by tough and elastic fibro-cartilages, as in the joints between the vertebral bodies and interpubic articulations; but in the *movable* joints the bones forming the articulation are generally expanded for greater convenience of mutual connection, covered by *cartilage*, held together by strong bands or capsules of fibrous tissue called *ligaments*, and partially lined by a membrane, the *synovial membrane*, which secretes a fluid to lubricate the various parts of which the joint is formed; so that the structures which enter into the formation of a joint are bone, cartilage, fibro-cartilage, ligament, and synovial membrane.

Bone constitutes the fundamental element of all the joints. In the long bones the extremities are the parts which form the articulations; they are generally somewhat enlarged, consisting of spongy cancellous tissue, with a thin coating of compact substance. In the flat bones the articulations usually take place at the edges, and, in the short bones at various parts of their surface. The layer of compact bone which forms the articular surface, and to which the cartilage is attached, is called the *articular lamella*. It is of a white color, extremely dense, and varies in thickness. Its structure differs from ordinary bone-tissue in this respect, that it contains no Haversian canals, and its lacunæ are much larger than in ordinary bone and have no canaliculi. The vessels of the cancellous tissue, as they approach the articular lamella, turn back in loops, and do not perforate it; this layer is consequently more dense and firmer than ordinary bone, and is evidently designed to form a firm and unyielding support for the articular cartilage.

The **cartilage**, which covers the articular surfaces of bone, and is called the *articular*, will be found described, with the other varieties of cartilage, in the section on General Anatomy.

Ligaments consist of bands of various forms, serving to connect together the articular extremities of bones, and composed mainly of bundles of *white fibrous tissue* placed parallel with, or closely interlaced with, one another, and presenting a white, shining, silvery aspect. A ligament is pliant and flexible, so as to allow of the most perfect freedom of movement, but strong, tough, and inextensible, so as not readily to yield under the most severely applied force; it is consequently well adapted to serve as the connecting medium between the bones. Some ligaments consist entirely of *yellow elastic tissue*, as the ligamenta subflava, which connect together the adjacent arches of the vertebræ and the ligamentum nuchæ in the lower animals. In these cases it will be observed that the elasticity of the ligament is intended to act as a substitute for muscular power.

Synovial membrane is a thin, delicate membrane of connective tissue, with branched connective-tissue corpuscles. Its secretion is thick, viscid, and glairy, like the white of egg, and is hence termed *synovia*. The synovial membranes found in the body admit of subdivision into three kinds—articular, bursal, and vaginal.

The *articular synovial membranes* are found in all the freely movable joints. In the fœtus this membrane is said, by Toynbee, to be continued over the surface

of the cartilages; but in the adult it is wanting, excepting at their circumference, upon which it encroaches for a short distance, and to which it is firmly attached; it then invests the inner surface of the capsular or other ligaments enclosing the joint, and is reflected over the surface of any tendons passing through its cavity, as the tendon of the Popliteus in the knee and the tendon of the Biceps in the shoulder. Hence the articular synovial membrane may be regarded as a short wide tube, attached by its open ends to the margins of the articular cartilages, and covering the inner surface of the various ligaments which connect the articular surfaces, so that along with the cartilages it completely encloses the joint-cavity. In some of the joints the synovial membrane is thrown into folds, which pass across the cavity. They are called *synovial ligaments*, and are especially distinct in the knee. In other joints there are flattened folds, subdivided at their margins into fringe-like processes, the vessels of which have a convoluted arrangement. These latter generally project from the synovial membrane near the margin of the cartilage and lie flat upon its surface. They consist of connective tissue covered with endothelium, and contain fat-cells in variable quantities, and, more rarely, isolated cartilage-cells. The larger folds often contain considerable quantities of fat. They were described by Clopton Havers as *mucilaginous glands*, and as the source of the synovial secretion. Under certain diseased conditions similar processes are found covering the entire surface of the synovial membrane, forming a mass of pedunculated fibro-fatty growths which project into the joint. Similar structures are also found in some of the bursal and vaginal synovial membranes.

The *bursal synovial membranes* are found interposed between surfaces which move upon each other, producing friction, as in the gliding of a tendon or of the integument over projecting bony surfaces. They admit of subdivision into two kinds, the *bursæ mucosæ* and the *bursæ synoviæ*. The *bursæ mucosæ* are large, simple, or irregular cavities in the subcutaneous areolar tissue, enclosing a clear viscid fluid. They are found in various situations, as between the integument and the front of the patella, over the olecranon, the malleoli, and other prominent parts. The *bursæ synoviæ* are found interposed between muscles or tendons as they play over projecting bony surfaces, as between the Glutei muscles and the surface of the great trochanter. They consist of a thin wall of connective tissue, partially covered by patches of cells, and contain a viscid fluid. Where one of these exists in the neighborhood of a joint, it may communicate with its cavity, as in the case of the bursa between the tendon of the Psoas and Iliacus and the capsular ligament of the hip, or the one interposed between the under surface of the Subscapularis and the neck of the scapula.

The *vaginal synovial membranes (synovial sheaths)* serve to facilitate the gliding of tendons in the osseo-fibrous canals through which they pass. The membrane is here arranged in the form of a sheath, one layer of which adheres to the wall of the canal, and the other is reflected upon the surface of the contained tendon, the space between the two free surfaces of the membrane containing synovia. These sheaths are chiefly found surrounding the tendons of the flexor and extensor muscles of the fingers and toes as they pass through the osseo-fibrous canals in the hand or foot.

Synovia is a transparent, yellowish-white or slightly reddish fluid, viscid like the white of egg, having an alkaline reaction and slightly saline taste. It consists, according to Frerichs, in the ox, of 94.85 water, 0.56 mucus and epithelium, 0.07 fat, 3.51 albumen and extractive matter, and 0.99 salts.

The articulations are divided into three classes: *synarthrosis*, or immovable; *amphiarthrosis*, or mixed; and *diarthrosis*, or movable joints.

1. Synarthrosis. Immovable Articulations.

Synarthrosis includes all those articulations in which the surfaces of the bones are in almost direct contact, fastened together by an intervening mass of connective tissue, and in which there is no appreciable motion, as the joints between the bones

of the cranium and face, excepting those of the lower jaw. The varieties of synarthrosis are four in number: Sutura, Schindylesis, Gomphosis, and Synchondrosis.

Sutura (a seam) is that form of articulation where the contiguous margins of flat bones are united by a thin layer of fibrous tissue. It is met with only in the skull. Where the articulating surfaces are connected by a series of processes and indentations interlocked together, it is termed *sutura vera*, of which there are three varieties: *sutura dentata*, *serrata*, and *limbosa*. The surfaces of the bones are not in direct contact, being separated by a layer of membrane continuous externally with the pericranium, internally with the dura mater. The *sutura dentata* (*dens*, a tooth) is so called from the tooth-like form of the projecting articular processes, as in the suture between the parietal bones. In the *sutura serrata* (*serra*, a saw) the edges of the two bones forming the articulation are serrated like the teeth of a fine saw, as between the two portions of the frontal bone. In the *sutura limbosa* (*limbus*, a selvage), besides the dentated processes, there is a certain degree of bevelling of the articular surfaces, so that the bones overlap one another, as in the suture between the parietal and frontal bones. When the articulation is formed by roughened surfaces placed in apposition with one another, it is termed the *false suture* (*sutura notha*), of which there are two kinds: the *sutura squamosa* (*squama*, a scale), formed by the overlapping of two contiguous bones by broad bevelled margins, as in the squamo-parietal (squamous) suture; and the *sutura harmonia* (*ἀρμονία*, a joining together), where there is simple apposition of two contiguous rough bony surfaces, as in the articulation between the two superior maxillary bones or of the horizontal plates of the palate bones.

Schindylesis (*σχινδύλεις*, a fissure) is that form of articulation in which a thin plate of bone is received into a cleft or fissure formed by the separation of two laminæ in another bone, as in the articulation of the rostrum of the sphenoid and perpendicular plate of the ethmoid with the vomer, or in the reception of the latter in the fissure between the superior maxillary and palate bones.

Gomphosis (*γόμφος*, a nail) is an articulation formed by the insertion of a conical process into a socket, as a nail is driven into a board; this is not illustrated by any articulation between bones, properly so called, but is seen in the articulation of the teeth with the alveoli of the maxillary bones.

Synchondrosis.—Where the connecting medium is cartilage the joint is termed a synchondrosis. This is a temporary form of joint, for the cartilage becomes converted into bone before adult life. Such a joint is found between the epiphyses and shafts of long bones.

2. Amphiarthrosis. Mixed Articulations.

In this form of articulation the contiguous osseous surfaces are either connected together by broad flattened disks of fibro-cartilage, of a more or less complex structure, which adhere to the end of each bone, as in the articulation between the bodies of the vertebræ and the pubic symphyses. This is termed **Symphysis**. Or, secondly, the bony surfaces are united by an interosseous ligament, as in the inferior tibio-fibular articulation. To this the term **Syndesmosis** is applied.

3. Diarthrosis. Movable Articulations.

This form of articulation includes the greater number of the joints in the body, mobility being their distinguishing character. They are formed by the approximation of two contiguous bony surfaces covered with cartilage, connected by ligaments and lined by synovial membrane. The varieties of joints in this class have been determined by the kind of motion permitted in each. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one form, the Ginglymus, this axis is, practically speaking, transverse; in the other, the trochoid or pivot-joint, it is longitudinal. There are two varieties where the movement is biaxial, or around two horizontal

axes at right angles to each other or at any intervening axis between the two. These are the condyloid and saddle-joint. There is one form of joint where the movement is polyaxial, the enarthrosis or ball-and-socket joint. And finally there are the Arthrodia or Gliding joints.

Ginglymus or Hinge-joint (γίγγλυμος, a hinge).—In this form of joint the articular surfaces are moulded to each other in such a manner as to permit motion only in one plane, forward and backward; the extent of motion at the same time being considerable. The direction which the distal bone takes in this motion is never in the same plane as that of the axis of the proximal bone, but there is always a certain amount of alteration from the straight line during flexion. The articular surfaces are connected together by strong lateral ligaments, which form their chief bond of union. The most perfect forms of ginglymus are the interphalangeal joints and the joint between the humerus and ulna; the knee and ankle are less perfect, as they allow a slight degree of rotation or lateral movement in certain positions of the limb.

Trochoides (pivot-joint).—Where the movement is limited to rotation, the joint is formed by a pivot-like process turning within a ring, or the ring on the pivot, the ring being formed partly of bone, partly of ligament. In the superior radio-ulnar articulation the ring is formed partly by the lesser sigmoid cavity of the ulna; in the rest of its extent, by the orbicular ligament; here the head of the radius rotates within the ring. In the articulation of the odontoid process of the axis with the atlas the ring is formed in front by the anterior arch of the atlas; behind, by the transverse ligament; here the ring rotates round the odontoid process.

Condyloid Articulations.—In this form of joint an ovoid articular head, or condyle, is received into an elliptical cavity in such a manner as to permit of flexion and extension, adduction and abduction and circumduction, but no axial rotation. The articular surfaces are connected together by anterior, posterior, and lateral ligaments. An example of this form of joint is found in the wrist.

Articulations by Reciprocal Reception (saddle-joint).—In this variety the articular surfaces are concavo-convex; that is to say, they are inversely convex in one direction and concave in the other. The movements are the same as in the preceding form; that is to say, there is flexion, extension, adduction, abduction, and circumduction, but no axial rotation. The articular surfaces are connected by a capsular ligament. The best example of this form of joint is the carpo-metacarpal joint of the thumb.

Enarthrosis is that form of joint in which the distal bone is capable of motion around an indefinite number of axes which have one common centre. It is formed by the reception of a globular head into a deep cup-like cavity (hence the name "ball-and-socket"), the parts being kept in apposition by a capsular ligament strengthened by accessory ligamentous bands. Examples of this form of articulation are found in the hip and shoulder.

Arthrodia is that form of joint which admits of a gliding movement; it is formed by the approximation of plane surfaces or one slightly concave, the other slightly convex, the amount of motion between them being limited by the ligaments, or osseous processes, surrounding the articulation; as in the articular processes of the vertebræ, the carpal joints, except that of the os magnum with the scaphoid and semilunar bones, and the tarsal joints with the exception of the joint between the astragalus and the navicular.

On the next page, in a tabular form, are the names, distinctive characters, and examples of the different kinds of articulations.

The Kinds of Movement admitted in Joints.

The movements admissible in joints may be divided into four kinds: gliding, angular movement, circumduction, and rotation. These movements are often, however, more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that we find only one kind of motion in any particular joint.

Synarthrosis, or Immovable Joint. Surfaces separated by fibrous membrane or by line of cartilage, without any intervening synovial cavity, and immovably connected with each other.

As in joints of cranium and face (except lower jaw).

Amphiarthrosis, Mixed Articulation.

Diarthrosis, Movable Joint.

Sutura. Articulation by processes and indentations interlocked together.

Sutura vera (true), articulate by indented borders.

Sutura notha (false), articulate by rough surfaces.

Dentata, having tooth-like processes. As in interparietal suture.

Serrata, having serrated edges like the teeth of a saw.

As in interfrontal suture.

Limboza, having bevelled margins and dentated processes.

As in fronto-parietal suture.

Squamosa, formed by thin bevelled margins, overlapping each other.

As in squamo-parietal suture.

Harmonia, formed by the apposition of contiguous rough surfaces.

As in intermaxillary suture.

Schindylesis.—Articulation formed by the reception of a thin plate of one bone into a fissure of another.

As in articulation of rostrum of sphenoid with vomer.

Gomphosis.—Articulation formed by the insertion of a conical process into a socket: the teeth.

Symphysis.—Surfaces connected by fibro-cartilage, not separated by synovial membrane, and having limited motion.

As in joints between bodies of vertebræ.

Syndesmosis.—Surfaces united by an interosseous ligament.

As in the inferior tibio-fibular articulation.

Ginglymus.—Hinge-joint; motion limited to two directions, forward and backward. Articular surfaces fitted together so as to permit of movement in one plane. As in the interphalangeal joints and the joint between the humerus and the ulna.

Trochoides, or Pivot-joint.—Articulation by a pivot process turning within a ring or ring around a pivot. As in superior radio-ulnar articulation and atlanto-axial joint.

Condylloid.—Ovoid head received into elliptical cavity. Movements in every direction except axial rotation. As the wrist-joint.

Reciprocal Reception (saddle-joint).—Articular surfaces inversely convex in one direction and concave in the other. Movement in every direction except axial rotation. As in the carpo-metacarpal joint of the thumb.

Enarthrosis.—Ball-and-socket joint; capable of motion in all directions. Articulations by a globular head received into a cup-like cavity. As in hip- and shoulder-joints.

Arthrodia.—Gliding joint; articulations by plane surfaces, which glide upon each other. As in carpal and tarsal articulations.

Gliding movement is the most simple kind of motion that can take place in a joint, one surface gliding or moving over another without any angular or rotatory movement. It is common to all movable joints, but in some, as in the articulations of the carpus and tarsus, it is the only motion permitted. This movement is not confined to plane surfaces, but may exist between any two contiguous surfaces, of whatever form, limited by the ligaments which enclose the articulation.

Angular movement occurs only between the long bones, and by it the angle between the two bones is increased or diminished. It may take place in four directions: forward and backward, constituting flexion and extension, or inward and outward, from the mesial line of the body (or in the fingers and toes from the middle line of the hand or foot), constituting adduction and abduction. The strictly ginglymoid or hinge-joints admit of flexion and extension only. Abduction and adduction, combined with flexion and extension, are met with in the more movable joints; as in the hip, shoulder, and metacarpal joint of the thumb, and partially in the wrist.

Circumduction is that limited degree of motion which takes place between the head of a bone and its articular cavity, whilst the extremity and sides of the limb are made to circumscribe a conical space, the base of which corresponds with the inferior extremity of the limb, the apex with the articular cavity; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is the movement of a bone upon an axis, which is the axis of the pivot on which the bone turns, as in the articulation between the atlas and axis, when the odontoid process serves as a pivot around which the atlas turns; or else is the axis of a pivot-like process which turns within a ring, as in the rotation of the radius upon the humerus.

Ligamentous Action of Muscles.—The movements of the different joints of a limb are combined by means of the long muscles which pass over more than one joint, and which, when relaxed and stretched to their greatest extent, act as elastic ligaments in restraining certain movements of one joint, except when combined with corresponding movements of the other, these latter movements being usually in the opposite direction. Thus the shortness of the hamstring muscles prevents complete flexion of the hip, unless the knee-joint is also flexed, so as to bring their attachments nearer together. The uses of this arrangement are threefold: 1. It co-ordinates the kinds of movement which are the most habitual and necessary, and enables them to be performed with the least expenditure of power. "Thus in the usual gesture of the arms, whether in grasping or rejecting, the shoulder and the elbow are flexed simultaneously, and simultaneously extended," in consequence of the passage of the Biceps and Triceps cubiti over both joints. 2. It enables the short muscles which pass over only one joint to act upon more than one. "Thus, if the Rectus femoris remain tonically of such length that, when stretched over the extended hip, it compels extension of the knee, then the Gluteus maximus becomes not only an extensor of the hip, but an extensor of the knee as well." 3. It provides the joints with ligaments which, while they are of very great power in resisting movements to an extent incompatible with the mechanism of the joint, at the same time spontaneously yield when necessary. "Taxed beyond its strength, a ligament will be ruptured, whereas a contracted muscle is easily relaxed; also, if neighboring joints be united by ligaments, the amount of flexion or extension of each must remain in constant proportion to that of the other; while, if the union be by muscles, the separation of the points of attachment of those muscles may vary considerably in different varieties of movement, the muscles adapting themselves tonically to the length required." The quotations are from a very interesting paper by Dr. Cleland in the *Journal of Anatomy and Physiology*, No. 1, 1866, p. 85; by whom I believe this important fact in the mechanism of joints was first clearly pointed out, though it has been independently observed afterward by other anatomists. Dr. W. W. Keen points out how important it is "that the surgeon should remember this ligamentous action of

muscles in making passive motion—for instance, at the wrist after Colles's fracture. If the fingers be extended, the wrist can be flexed to a right angle. If, however, they be first flexed, as in "making a fist," flexion at the wrist is quickly limited to from forty to fifty degrees in different persons, and is very painful beyond that point. Hence passive motion here should be made with the fingers extended. In the leg, when flexing the hip, the knee should be flexed." Dr. Keen further points out that "a beautiful illustration of this is seen in the perching of birds, whose toes are forced to clasp the perch by just such a passive ligamentous action so soon as they stoop. Hence they can go to sleep and not fall off the perch."

The articulations may be arranged into those of the trunk, those of the upper extremity, and those of the lower extremity.

ARTICULATIONS OF THE TRUNK.

These may be divided into the following groups, viz.:

- | | |
|--|--|
| I. Of the vertebral column. | VII. Of the cartilages of the ribs with the sternum and with each other. |
| II. Of the atlas with the axis. | VIII. Of the sternum. |
| III. Of the atlas with the occipital bone. | IX. Of the vertebral column with the pelvis. |
| IV. Of the axis with the occipital bone. | X. Of the pelvis. |
| V. Of the lower jaw. | |
| VI. Of the ribs with the vertebræ. | |

I. Articulations of the Vertebral Column.

The different segments of the spine are connected together by ligaments, which may be divided into five sets: 1. Those connecting the *bodies* of the vertebræ. 2. Those connecting the *laminae*. 3. Those connecting the *articular processes*. 4. Those connecting the *spinous processes*. 5. Those of the *transverse processes*.

The articulations of the *bodies* of the vertebræ with each other form a series of amphiarthrodial joints; those between the *articular processes* form a series of arthrodial joints.

1. THE LIGAMENTS OF THE BODY.

Anterior Common Ligament.

Posterior Common Ligament.

Intervertebral Substance.

The **Anterior Common Ligament** (Figs. 152, 153, 160, 164) is a broad and strong band of fibres which extends along the anterior surface of the bodies of the vertebræ from the axis to the sacrum. It is broader below than above, thicker in the dorsal than in the cervical or lumbar regions, and somewhat thicker opposite the front of the body of each vertebra than opposite the intervertebral substance. It is attached, above, to the body of the axis by a pointed process, where it is continuous with the anterior atlanto-axial ligament, and is connected with the tendon of insertion of the *Longus colli* muscle, and extends down as far as the upper bone of the sacrum. It consists of dense longitudinal fibres, which are intimately adherent to the intervertebral substance and the prominent margins of the vertebræ, but less closely to the middle of the bodies. In the latter situation the fibres are exceedingly thick, and serve to fill up the concavities on their front surface and to make the anterior surface of the spine more even. This ligament is composed of several layers of fibres, which vary in length, but are closely interlaced with each other. The most superficial or longest fibres extend between four or five vertebræ. A second subjacent set extend between two or three vertebræ, whilst a third set, the shortest and deepest, extend from one vertebra to the next. At the side of the bodies the ligament consists of a few short fibres, which pass from one vertebra to the next, separated from the median portion by large oval apertures for the passage of vessels.

The **Posterior Common Ligament** (Figs. 152, 156) is situated within the spinal

canal, and extends along the posterior surface of the bodies of the vertebræ from the body of the axis above, where it is continuous with the occipito-axial ligament, to the sacrum below. It is broader above than below, and thicker in the dorsal than in the cervical or lumbar regions. In the situation of the intervertebral substance and contiguous margins of the vertebræ, where the ligament is more intimately adherent, it is broad, and presents a series of dentations with intervening concave margins; but it is narrow and thick over the centre of the bodies, from which it is separated by the *venæ basis vertebræ*. This ligament is composed of smooth, shining, longitudinal fibres, denser and more compact than those of the anterior ligament, and composed of a superficial layer occupying the interval between three or four vertebræ, and of a deeper layer which extends between one vertebra and the next adjacent to it. It is separated from the dura mater of

FIG. 152.—Vertical section of two vertebræ and their ligaments, from the lumbar region.

the spinal cord by some loose connective tissue which is very liable to serous infiltration.

The **Intervertebral Substance** (Figs. 152, 161) is a lenticular disk of composite structure interposed between the adjacent surfaces of the bodies of the vertebræ from the axis to the sacrum, and forming the chief bond of connection between those bones. These disks vary in shape, size, and thickness in different parts of the spine. In *shape* they accurately correspond with the surfaces of the bodies between which they are placed, being oval in the cervical and lumbar regions, and circular in the dorsal. Their *size* is greatest in the lumbar region. In *thickness* they vary not only in the different regions of the spine, but in different parts of the same disk: thus, they are thicker in front than behind in the cervical and lumbar regions, while they are uniformly thick in the dorsal region. The intervertebral disks form about one-fourth of the spinal column, exclusive of the first two vertebræ; they are not equally distributed, however, between the various bones; the dorsal portion of the spine having, in proportion to its length, a much smaller quantity than in the cervical and lumbar regions, which necessarily gives to the latter parts greater pliancy and freedom of movement. The intervertebral disks are adherent, by their surfaces, to a thin layer of hyaline cartilage which covers the upper and under surfaces of the bodies of the vertebræ, and in which, in early life, the epiphyseal plate develops, and by their circumference are closely connected in

front to the anterior, and behind to the posterior common ligament; whilst in the dorsal region they are connected laterally, by means of the interarticular ligament, to the heads of those ribs which articulate with two vertebræ; they, consequently, form part of the articular cavities in which the heads of these bones are received.

Structure of the Intervertebral Substance.—The intervertebral substance is composed, at its circumference, of laminæ of fibrous tissue and fibro-cartilage; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish color, which rises up considerably above the surrounding level when the disk is divided horizontally. This pulpy substance, which is especially well developed in the lumbar region, is the remains of the chorda dorsalis, and, according to Luschka, contains a small synovial cavity in its centre. The laminæ are arranged concentrically one within the other, the outermost consisting of ordinary fibrous tissue, but the others and more numerous consisting of white fibro-cartilage. These plates are not quite vertical in their direction, those near the circumference being curved outward and closely approximated; whilst those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres of which each plate is composed are directed, for the most part, obliquely from above downward, the fibres of adjacent plates passing in opposite directions and varying in every layer; so that the fibres of one layer are directed across those of another, like the limbs of the letter X. This laminar arrangement belongs to about the outer half of each disk. The pulpy substance presents no concentric arrangement, and consists of a fine fibrous matrix, containing angular cells, united to form a reticular structure.

2. LIGAMENTS CONNECTING THE LAMINÆ.

Ligamenta Subflava.

The **Ligamenta Subflava** (Fig. 152) are interposed between the laminæ of the vertebræ, from the axis to the sacrum. They are most distinct when seen from the interior of the spinal canal; when viewed from the outer surface they appear short, being overlapped by the laminæ. Each ligament consists of two lateral portions, which commence on each side at the root of either articular process, and pass backward to the point where the laminæ converge to form the spinous process, where their margins are in contact and to a certain extent united; slight intervals being left for the passage of small vessels. These ligaments consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the anterior surface of the laminæ above, some distance from its inferior margin, and to the posterior surface, as well as to the margin of the lamina below. In the cervical region they are thin in texture, but very broad and long; they become thicker in the dorsal region, and in the lumbar acquire very considerable thickness. Their highly elastic property serves to preserve the upright posture and to assist in resuming it after the spine has been flexed. These ligaments do not exist between the occiput and atlas or between the atlas and axis.

3. LIGAMENTS CONNECTING THE ARTICULAR PROCESSES.

Capsular.

The **Capsular Ligaments** (Fig. 154) are thin and loose ligamentous sacs, attached to the contiguous margins of the articulating processes of each vertebra through the greater part of their circumference, and completed internally by the ligamenta subflava. They are longer and looser in the cervical than in the dorsal or lumbar regions. The capsular ligaments are lined on their inner surface by synovial membrane.

4. LIGAMENTS CONNECTING THE SPINOUS PROCESSES.

Supraspinous.

Interspinous.

The **Supraspinous Ligament** (Fig. 152) is a strong fibrous cord, which connects

together the apices of the spinous processes from the seventh cervical to the spinous processes of the sacrum. It is thicker and broader in the lumbar than in the dorsal region, and intimately blended, in both situations, with the neighboring aponeurosis. The most superficial fibres of this ligament connect three or four vertebræ; those deeper-seated pass between two or three vertebræ; whilst the deepest connect the contiguous extremities of neighboring vertebræ. It is continued upward to the external occipital protuberance, as the ligamentum nuchæ, which, in the human subject, is thin and forms merely an intermuscular septum.

The **Interspinous Ligaments** (Fig. 152), thin and membranous, are interposed between the spinous processes. Each ligament extends from the root to the summit of each spinous process and connects together their adjacent margins. They meet the ligamenta subflava in front and the supra-spinous ligament behind. They are narrow and elongated in the dorsal region; broader, quadrilateral in form, and thicker in the lumbar region; and only slightly developed in the neck.

5. LIGAMENTS CONNECTING THE TRANSVERSE PROCESSES.

Intertransverse.

The **Intertransverse Ligaments** consist of bundles of fibres interposed between the transverse processes. In the cervical region they consist of a few irregular, scattered fibres; in the dorsal, they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

Actions.—The movements permitted in the spinal column are, Flexion, Extension, Lateral Movement, Circumduction, and Rotation.

In *Flexion*, or movement of the spine forward, the anterior common ligament is relaxed, and the intervertebral substances are compressed in front, while the posterior common ligament, the ligamenta subflava, and the inter- and supra-spinous ligaments are stretched, as well as the posterior fibres of the intervertebral disks. The interspaces between the laminæ are widened, and the inferior articular processes of the vertebræ above glide upward upon the articular processes of the vertebræ below. Flexion is the most extensive of all the movements of the spine.

In *Extension*, or movement of the spine backward, an exactly opposite disposition of the parts takes place. This movement is not extensive, being limited by the anterior common ligament and by the approximation of the spinous processes.

Flexion and extension are free in the lower part of the lumbar region between the third and fourth and fourth and fifth lumbar vertebræ; above the third they are much diminished, and reach their minimum in the middle and upper part of the back. They increase again in the neck, the capability of motion backward from the upright position being in this region greater than that of the motion forward, whereas in the lumbar region the reverse is the case.

In *Lateral Movement*, the sides of the intervertebral disks are compressed, the extent of motion being limited by the resistance offered by the surrounding ligaments and by the approximation of the transverse processes. This movement may take place in any part of the spine, but is most free in the neck and loins.

Circumduction is very limited, and is produced merely by a succession of the preceding movements.

Rotation is produced by the twisting of the intervertebral substances; this, although only slight between any two vertebræ, produces a considerable extent of movement when it takes place in the whole length of the spine, the front of the upper part of the column being turned to one or the other side. This movement takes place only to a slight extent in the neck, but is freer in the upper part of the dorsal region, and is altogether absent in the lumbar region.

It is thus seen that the *cervical region* enjoys the greatest extent of each variety of movement, flexion and extension especially being very free. In the *dorsal region* the three movements of flexion, extension, and circumduction are permitted only to a slight extent, while rotation is very free in the upper part and

ceases below. In the lumbar region there is free flexion, extension, and lateral movement, but no rotation.

As Sir George Humphry has pointed out, the movements permitted are mainly due to the shape and position of the articulating processes. In the loins the inferior articulating processes are turned outward and embraced by the superior; this renders rotation in this region of the spine impossible, while there is nothing to prevent a sliding upward and downward of the surfaces on each other, so as to allow of flexion and extension. In the dorsal region, on the other hand, the articulating processes, by their direction and mutual adaptation, especially at the upper part of the series, permit of rotation, but prevent extension and flexion, while in the cervical region the greater obliquity and lateral slant of the articular processes allow not only flexion and extension, but also rotation.

The principal muscles which produce *flexion* are the Sterno-mastoid, Rectus capitis anticus major, and Longus colli; the Scaleri; the abdominal muscles and the Psoas magnus. *Extension* is produced by the fourth layer of the muscles of the back, assisted in the neck by the Splenius, Semispinalis dorsi et colli, and the Multifidus spinæ. *Lateral* motion is produced by the fourth layer of the muscles of the back, by the Splenius and the Scaleri, the muscles of one side only acting; and *rotation* by the action of the following muscles of one side only—viz. the Sterno-mastoid, the Rectus capitis anticus major, the Scaleri, the Multifidus spinæ, the Complexus, and the abdominal muscles.

II. Articulation of the Atlas with the Axis.

The articulation of the Atlas with the Axis is of a complicated nature, comprising no fewer than four distinct joints. There is a pivot articulation between the odontoid process of the axis and the ring formed between the anterior arch of the atlas and the transverse ligament (see Fig. 155). Here there are two joints: one in front between the posterior surface of the anterior arch of the atlas and the front of the odontoid process (the *atlanto-odontoid joint of Cruveilhier*); the other between the anterior surface of the transverse ligament and the back of the process (the *syndesmo-odontoid joint*). Between the articular processes of the two bones there is a double arthrodia or gliding joint. The ligaments which connect these bones are the

Anterior Atlanto-axial.
Posterior Atlanto-axial.

Transverse.
Two Capsular.

The **Anterior Atlanto-axial Ligament** (Fig. 153) is a strong, membranous layer, attached, above, to the lower border of the anterior arch of the atlas; below, to the base of the odontoid process and to the front of the body of the axis. It is strengthened in the middle line by a rounded cord, which is attached, above, to the tubercle on the anterior arch of the atlas, and below to the body of the axis, being a continuation upward of the anterior common ligament of the spine. These ligaments are in relation, in front, with the Recti antici majores.

The **Posterior Atlanto-axial Ligament** (Fig. 154) is a broad and thin membranous layer, attached, above, to the lower border of the posterior arch of the atlas; below, to the upper edge of the laminæ of the axis. This ligament supplies the place of the ligamenta subflava, and is in relation, behind, with the Inferior oblique muscles.

The **Transverse Ligament**¹ (Figs. 155, 156) is a thick, strong band, which arches across the ring of the atlas, and serves to retain the odontoid process in firm connection with its anterior arch. This ligament is flattened from before backward, broader and thicker in the middle than at either extremity, and firmly attached on

¹ It has been found necessary to describe the transverse ligament with those of the atlas and axis; but the student must remember that it is really a portion of the mechanism by which the movements of the head on the spine are regulated; so that the connections between the atlas and axis ought always to be studied together with those between the latter bones and the skull.

each side to a small tubercle on the inner surface of the lateral mass of the atlas. As it crosses the odontoid process, a small fasciculus is derived from its upper, and another from its lower, border; the former passing upward, to be inserted into the basilar process of the occipital bone; the latter, downward, to be attached to the posterior surface of the body of the axis; hence, the whole ligament has received the name of *cruciform*. The transverse ligament divides the ring of the atlas into two unequal parts: of these, the posterior and larger serves for the transmission of the cord and its membranes and the spinal accessory nerves; the anterior and smaller contains the odontoid process. Since the space between the anterior arch of the atlas and the transverse ligament is smaller at the lower

FIG. 153.—Occipito-atlantal and atlanto-axial ligaments. Front view.

part than the upper (because the transverse ligament embraces firmly the narrow neck of the odontoid process), this process is retained in firm connection with the atlas after all the other ligaments have been divided.

The **Capsular Ligaments** are two thin and loose capsules, connecting the lateral masses of the atlas with the superior articular surfaces of the axis, the fibres being strengthened at the posterior and inner part of the articulation by an *accessory ligament*, which is attached below to the body of the axis near the base of the odontoid process.

There are **four Synovial Membranes** in this articulation: one lining the inner surface of each of the capsular ligaments; one between the anterior surface of the odontoid process and the anterior arch of the atlas, the *atlanto-odontoid joint*; and one between the posterior surface of the odontoid process and the transverse ligament, the *syndesmo-odontoid joint*. The latter often communicates with those between the condyles of the occipital bone and the articular surfaces of the atlas.

Actions.—This joint allows the rotation of the atlas (and, with it, of the cranium) upon the axis, the extent of rotation being limited by the odontoid ligaments.

The principal muscles by which this action is produced are the Sterno-mastoid and Complexus of one side, acting with the Rectus capitis anticus major, Splenius, Trachelo-mastoid, Rectus capitis posticus major, and Inferior oblique of the other side.

ARTICULATIONS OF THE SPINE WITH THE CRANIUM.

The ligaments connecting the spine with the cranium may be divided into two sets—those connecting the occipital bone with the atlas, and those connecting the occipital bone with the axis.

III. Articulation of the Atlas with the Occipital Bone.

This articulation is a double condyloid joint. Its ligaments are the

Anterior Occipito-atlantal.
Posterior Occipito-atlantal.

Two Lateral Occipito-atlantal.
Two Capsular.

The **Anterior Occipito-atlantal Ligament** (Fig. 153) is a broad membranous layer, composed of densely woven fibres, which passes between the anterior

FIG. 154.—Occipito-atlantal and atlanto-axial ligaments. Posterior view.

margin of the foramen magnum above, and the whole length of the upper border of the anterior arch of the atlas below. Laterally, it is continuous with the capsular ligaments. In the middle line in front it is strengthened by a strong, narrow, rounded cord, which is attached, above, to the basilar process of the occiput, and, below, to the tubercle on the anterior arch of the atlas. This ligament is in relation, in front, with the Recti antici minores; behind, with the odontoid ligaments.

The **Posterior Occipito-atlantal Ligament** (Fig. 154) is a very broad but thin membranous lamina intimately blended with the dura mater. It is connected, above, to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. This ligament is incomplete at each side, and forms, with the superior intervertebral notch, an opening for the passage of the vertebral artery and suboccipital nerve. The fibrous band which arches over the artery and nerve sometimes becomes ossified. It is in relation, behind, with the Recti postici minores and Obliqui superiores; in front, with the dura mater of the spinal canal, to which it is intimately adherent.

The **Lateral Ligaments** are strong fibrous bands, directed obliquely upward and

inward, attached above to the jugular process of the occipital bone; below, to the base of the transverse process of the atlas.

The **Capsular Ligaments** surround the condyles of the occipital bone, and connect them with the articular processes of the atlas; they consist of thin and loose capsules, which enclose the synovial membrane of the articulation.

Synovial Membranes.—There are two synovial membranes in this articulation, one lining the inner surface of each of the capsular ligaments. These occasionally communicate with that between the posterior surface of the odontoid process and the transverse ligament.

Actions.—The movements permitted in this joint are flexion and extension, which give rise to the ordinary forward and backward nodding of the head, besides

FIG. 155.—Articulation between odontoid process and atlas.

slight lateral motion to one or the other side. When either of these actions is carried beyond a slight extent, the whole of the cervical portion of the spine assists in its production. Flexion is mainly produced by the action of the Rectus capitis anticus major et minor and the Sterno-mastoid muscles; extension by the Rectus capitis posticus major et minor, the Superior oblique, the Complexus, Splenius, and upper fibres of the Trapezius. The Recti laterales are concerned in the lateral movement, assisted by the Trapezius, Splenius, Complexus, and the Sterno-mastoid of the same side, all acting together. According to Cruveilhier, there is a slight motion of rotation in this joint.

IV. Articulation of the Axis with the Occipital Bone.

Occipito-axial.

Three Odontoid.

To expose these ligaments the spinal canal should be laid open by removing the posterior arch of the atlas, the laminae and spinal process of the axis, and the portion of the occipital bone behind the foramen magnum, as seen in Fig. 156.

The **Occipito-axial Ligament** (*apparatus ligamentosus colli*) is situated within the spinal canal. It is a broad, strong band, which covers the odontoid process and its ligaments, and appears to be a prolongation upward of the posterior common ligament of the spine. It is attached, below, to the posterior surface of the body of the axis, and, becoming expanded as it ascends, is inserted into the basilar groove of the occipital bone, in front of the foramen magnum, where it becomes blended with the dura mater of the skull.

Relations.—By its anterior surface with the transverse ligament; by its posterior surface with the dura mater.

The **Odontoid or Check Ligaments** (*alar ligaments*) are strong, rounded, fibrous cords, which arise one on either side of the upper part of the odontoid process, and, passing obliquely upward and outward, are inserted into the rough depressions on the inner side of the condyles of the occipital bone. In the triangular interval left between these ligaments another strong fibrous cord (*ligamentum suspensorium*, or

middle odontoid ligament) may be seen, which passes almost perpendicularly from the apex of the odontoid process to the anterior margin of the foramen magnum, being intimately blended with the deep portion of the anterior occipito-atlantal ligament and upper fasciculus of the transverse ligament of the atlas.

Actions.—The odontoid ligaments serve to limit the extent to which rotation

FIG. 156.—Occipito-axial and atlanto-axial ligaments. Posterior view, obtained by removing the arches of the vertebrae and the posterior part of the skull.

of the cranium may be carried; hence they have received the name of *check ligaments*.

In addition to these ligaments, which connect the atlas and axis to the skull, the ligamentum nuchæ must be regarded as one of the ligaments by which the spine is connected with the cranium. It is described on a subsequent page.

Surgical Anatomy.—The ligaments which unite the component parts of the vertebrae together are so strong, and these bones are so interlocked by the arrangement of their articulating processes, that dislocation is very uncommon, and, indeed, unless accompanied by fracture, rarely occurs, except in the upper part of the neck. Dislocation of the occiput from the atlas has only been recorded in one or two cases; but dislocation of the atlas from the axis, with rupture of the transverse ligament, is much more common: it is the mode in which death is produced in many cases of execution by hanging. In the lower part of the neck—that is, below the third cervical vertebra—dislocation unattended by fracture occasionally takes place.

V. Articulation of the Lower Jaw (Temporo-mandibular).

This is a ginglymo-arthrodial joint: the parts entering into its formation on each side are, above, the anterior part of the glenoid cavity of the temporal bone and the eminentia articularis; and, below, the condyle of the lower jaw. The ligaments are the following:

External Lateral.

Stylo-mandibular.

Internal Lateral.

Capsular.

Interarticular Fibro-cartilage.

The **External Lateral Ligament** (Fig. 157) is a short, thin, and narrow fasciculus, attached, above, to the outer surface of the zygoma and to the tubercle on its lower border; below, to the outer surface and posterior border of the neck of the lower jaw. It is broader above than below; its fibres are placed

parallel with one another, and directed obliquely downward and backward. Externally, it is covered by the parotid gland and by the integument. Internally,

FIG. 157.—Temporo-mandibular articulation. External view.

it is in relation with the capsular ligament, of which it is an accessory band, and not separable from it.

The **Internal Lateral Ligament** (*Spheno-mandibular*) (Fig. 158) is a flat, thin band which is attached above to the spinous process of the sphenoid bone, and, becoming broader as it descends, is inserted into the lingula and margin of the dental foramen. Its outer surface is in relation, above, with the External pterygoid muscle; lower down it is separated from the neck of the condyle by the internal maxillary artery; and still more inferiorly, the inferior dental vessels and nerve separate it from the ramus of the jaw. The inner surface is in relation with the Internal pterygoid. It is really the fibrous covering of a part of Meckel's cartilage.

FIG. 158.—Temporo-mandibular articulation. Internal view.

The **Stylo-mandibular Ligament** is a specialized band of the cervical fascia, which extends from near the apex of the styloid process of the temporal bone to the angle and posterior border of the ramus of the lower jaw, between the Masseter and Internal pterygoid muscles.

This ligament separates the parotid from the submaxillary gland, and has attached to its inner side part of the fibres of origin of the Stylo-glossus muscle. Although

usually classed among the ligaments of the jaw, it can be considered only as an accessory to the articulation.

The **Capsular Ligament** forms a thin and loose capsule, attached above to the circumference of the glenoid cavity and the articular surface immediately in front; below, to the neck of the condyle of the lower jaw. It consists of a few thin scattered fibres, and can hardly be considered as a distinct ligament; it is thickest at the back part of the articulation.¹

The **Interarticular Fibro-cartilage** (Fig. 159) is a thin plate of an oval form, placed horizontally between the condyle of the jaw and the glenoid cavity. Its upper surface is concavo-convex from before backward, and a little convex transversely, to accommodate itself to the form of the glenoid cavity. Its under surface, where it is in contact with the condyle, is concave. Its circumference is connected to the capsular ligament, and in front to the tendon of the External pterygoid muscle. It is thicker at its circumference, especially behind, than at its centre. The fibres of which it is composed have a concentric arrangement, more apparent at the circumference than at the centre. Its surfaces are smooth. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

FIG. 159.—Vertical section of temporo-mandibular articulation.

The **Synovial Membranes**, two in number, are placed, one above, and the other below, the fibro-cartilage. The upper one, the larger and looser of the two, is continued from the margin of the cartilage covering the glenoid cavity and eminentia articularis on to the upper surface of the fibro-cartilage. The lower one passes from the under surface of the fibro-cartilage to the neck of the condyle of the jaw, being prolonged downward a little farther behind than in front. The interarticular cartilage is sometimes perforated in its centre; the two synovial sacs then communicate with each other.

The *nerves* of this joint are derived from the auriculo-temporal and masseteric branches of the inferior maxillary. The *arteries* are derived from the temporal branch of the external carotid.

Actions.—The movements permitted in this articulation are very extensive. Thus, the jaw may be depressed or elevated, or it may be carried forward or backward. It must be borne in mind that there are two distinct joints in this articulation—that is to say, one between the condyle of the jaw and the interarticular fibro-cartilage, and another between the fibro-cartilage and the glenoid fossa; when the jaw is depressed, as in opening the mouth, the movements which take place in these two joints are not the same. In the lower compartment, that between the condyle and the fibro-cartilage, the movement is of a ginglymoid or hinge-like character, the condyle rotating on a transverse axis on the fibro-cartilage; while in the upper compartment the movement is of a gliding character, the fibro-cartilage, together with the condyle, gliding forward on to the eminentia articularis. These two movements take place simultaneously—the condyle and fibro-cartilage move forward on the eminence, and at the same time the condyle revolves on the fibro-cartilage. In the opposite movement of shutting the mouth the reverse action takes place; the fibro-cartilage glides back, carrying the condyle with it, and this at the same time revolves back to its former position. When the jaw is carried horizontally forward, as in protruding the lower incisors in front of the upper, the move-

¹ Sir G. Humphry describes the internal portion of the capsular ligament separately as the short internal lateral ligament and it certainly seems as deserving of a separate description as the external lateral ligament is.

ment takes place principally in the upper compartment of the joint: the fibro-cartilage, carrying with it the condyle, glides forward on the glenoid fossa. This is because this movement is mainly effected by the External pterygoid muscles, which are inserted into both condyle and interarticular fibro-cartilage. The grinding or chewing movement is produced by the alternate movement of one condyle, with its fibro-cartilage, forward and backward, while the other condyle moves simultaneously in the opposite direction; at the same time the condyle undergoes a vertical rotation on its own axis on the fibro-cartilage in the lower compartment. One condyle advances and rotates, the other condyle recedes and rotates, in alternate succession.

The lower jaw is *depressed* by its own weight, assisted by the Platysma, the Digastric, the Mylo-hyoid, and the Genio-hyoid. It is *elevated* by the anterior part of the Temporal, Masseter, and Internal pterygoid. It is drawn *forward* by the simultaneous action of the External pterygoid and the superficial fibres of the Masseter; and it is drawn *backward* by the deep fibres of the Masseter and the posterior fibres of the Temporal muscle. The grinding movement is caused by the alternate action of the two External pterygoids.

Surface Form.—The temporo-mandibular articulation is quite superficial, situated below the base of the zygoma, in front of the tragus and external auditory meatus, and behind the posterior border of the upper part of the Masseter muscle. Its exact position can be at once ascertained by feeling for the condyle of the jaw, the working of which can be distinctly felt in the movements of the lower jaw in opening and shutting the mouth. When the mouth is opened wide, the condyle advances out of the glenoid fossa on to the eminentia articularis, and a depression is felt in the situation of the joint.

Surgical Anatomy.—The lower jaw is dislocated only in one direction—viz. forward. The accident is caused by violence or muscular action. When the mouth is open, the condyle is situated on the eminentia articularis, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace the condyle forward into the zygomatic fossa. The displacement may be unilateral or bilateral, according as one or both of the condyles are displaced. The latter of the two is the more common.

Sir Astley Cooper described a condition which he termed “subluxation.” It occurs principally in delicate women, and is believed by some to be due to the relaxation of the ligaments, permitting too free movement of the bone, and possibly some displacement of the fibro-cartilage. Others have believed that it is due to gouty or rheumatic changes in the joint. In close relation to the condyle of the jaw is the external auditory meatus and the tympanum; any force, therefore, applied to the bone is liable to be attended with damage to these parts, or inflammation in the joint may extend to the ear, or on the other hand inflammation of the middle ear may involve the articulation and cause its destruction, thus leading to ankylosis of the joint. In children, arthritis of this joint may follow the exanthemata, and in adults it occurs as the result of some constitutional conditions, as rheumatism or gout. The temporo-mandibular joint is also occasionally the seat of osteo-arthritis, leading to great suffering during efforts of mastication. A peculiar affection sometimes attacks the neck and condyle of the lower jaw, consisting in hypertrophy and elongation of these parts and consequent protrusion of the chin to the opposite side.

VI. Articulations of the Ribs with the Vertebrae.

The articulations of the ribs with the vertebral column may be divided into two sets: 1. Those which connect the heads of the ribs with the bodies of the vertebrae, *costo-central*. 2. Those which connect the necks and tubercles of the ribs with the transverse processes, *costo-transverse*.

1. ARTICULATIONS BETWEEN THE HEADS OF THE RIBS AND THE BODIES OF THE VERTEBRÆ (Fig. 160).

These constitute a series of arthrodial joints, formed by the articulation of the heads of the ribs with the cavities on the contiguous margins of the bodies of the dorsal vertebrae and the intervertebral substance between them, except in the case of the first, tenth, eleventh, and twelfth ribs, where the cavity is formed by a single vertebra. The bones are connected by the following ligaments:

Anterior Costo-vertebral or Stellate.

Capsular.

Interarticular.

The **Anterior Costo-vertebral or Stellate Ligament** connects the anterior part of

the head of each rib with the sides of the bodies of two vertebræ and the intervertebral disk between them. It consists of three flat bundles of ligamentous fibres, which are attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres pass upward to be connected with the body of the vertebra above; the inferior one descends to the body of the vertebra below; and the middle one, the smallest and least distinct, passes horizontally inward, to be attached to the intervertebral substance.

Relations.—In front, with the thoracic ganglia of the sympathetic, the pleura, and, on the right side, with the vena azygos major; behind, with the interarticular ligament and synovial membranes.

In the first rib, which articulates with a single vertebra, this ligament does not present a distinct division into three fasciculi; its fibres, however, radiate, and are attached to the body of the last cervical vertebra, as well as to the body of the vertebra with which the rib articulates. In the tenth, eleventh, and twelfth ribs also, which likewise articulate with a single vertebra, the division does not exist; but the fibres of the ligament in each case radiate and are connected with the vertebra above, as well as that with which the ribs articulate.

The **Capsular Ligament** is a thin and loose ligamentous bag, which surrounds the joint between the head of the rib and the articular cavity formed by the intervertebral disk and the adjacent vertebra. It is very thin, firmly connected with the anterior ligament, and most distinct at the upper and lower parts of the articulation. Behind, some of its fibres pass through the intervertebral foramen to the back of the intervertebral disk. This is the analogue of the *ligamentum conjugale* of some mammals, which unites the heads of opposite ribs across the back of the intervertebral disk.

The **Interarticular Ligament** is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downward, attached by one extremity to the sharp crest which separates the two articular facets on the head of the rib, and by the other to the intervertebral disk. It divides the joint into two cavities, which have no communication with each other. In the first, tenth, eleventh, and twelfth ribs the interarticular ligament does not exist; consequently there is but one synovial membrane.

The **Synovial Membrane**.—There are two synovial membranes in each of the articulations in which there is an interarticular ligament, one on each side of this structure.

FIG. 160.—Costo-vertebral and costo-transverse articulations. Anterior view.

2. ARTICULATIONS OF THE NECKS AND TUBERCLES OF THE RIBS WITH THE TRANSVERSE PROCESSES (Fig. 161).

The articular portion of the tubercle of the rib and adjacent transverse process form an arthrodial joint.

In the *eleventh* and *twelfth ribs* this articulation is wanting.

The ligaments connecting these parts are the—

Anterior Costo-transverse.
Middle Costo-transverse (Interosseous).
Posterior Costo-transverse.
Capsular.

The **Anterior Costo-transverse Ligament** (*superior* or *long*) consists of two sets of fibres: the one (*anterior*) is attached below to the sharp crest on the upper border of the neck of each rib, and passes obliquely upward and outward to the lower border of the transverse process immediately above; the other (*posterior*) is attached below to the neck of the rib, and passes upward and inward to the base of the transverse process and outer border of the lower articular process of the vertebra above. This ligament is in relation, in front, with the intercostal vessels and nerves; behind, with the Longissimus dorsi. Its *internal border* is thickened and free, and bounds an aperture through which pass the posterior branches of the intercostal vessels and nerves. Its *external border* is continuous with a thin aponeurosis which covers the External intercostal muscle.

The *first rib* has no anterior costo-transverse ligament.

The **Middle Costo-transverse** or **Interosseous Ligament** consists of short but strong fibres which pass between the rough surface on the posterior part of the neck of each rib and the anterior surface of the adjacent transverse process. In

FIG. 161.—Costo-transverse articulation. Seen from above.

order fully to expose this ligament, a horizontal section should be made across the transverse process and corresponding part of the rib; or the rib may be forcibly separated from the transverse process and its fibres put on the stretch.

In the *eleventh* and *twelfth ribs* this ligament is quite rudimentary or wanting.

The **Posterior Costo-transverse Ligament** is a short but thick and strong fasciculus which passes obliquely from the summit of the transverse process to the rough non-articular portion of the tubercle of the rib. This ligament is shorter and more oblique in the upper than in the lower ribs. Those corresponding to the superior ribs ascend, while those of the inferior ribs descend slightly.

In the *eleventh* and *twelfth ribs* this ligament is wanting.

The **Capsular Ligament** is a thin, membranous sac attached to the circumference of the articular surfaces, and enclosing a small synovial membrane.

In the *eleventh* and *twelfth ribs* this ligament is absent.

Actions.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the stellate and interarticular ligaments, and the necks and tubercles of the ribs to the transverse processes, that only a slight sliding movement of the articular surfaces on each other can take place in these articulations. The result of this gliding movement with respect to the six upper ribs consists in an elevation of the front and middle portion of the rib, the hinder part being prevented from performing any upward movement by its close connection with the spine. In this gliding movement the rib rotates on an axis corresponding with a line drawn through the two articulations, Costo-central and Costo-transverse, which the rib forms with the spine. With respect to the seventh, eighth, ninth, and tenth ribs, each one, besides rotating in a similar manner to the upper six, also rotates on an axis corresponding with a line drawn from the head of the rib to the sternum. By the first movement—that of rotation of the rib on an axis corresponding with a line drawn through the two articulations which this bone forms with the spine—an elevation of the anterior part of the rib takes place, and a consequent enlargement of the antero-posterior diameter of the chest. None of the ribs lie in a truly horizontal plane; they are all directed more or less obliquely, so that their anterior extremities lie on a lower level than their posterior, and this obliquity increases from the first to the seventh, and then again decreases. If we examine any one rib—say, that in which there is the greatest obliquity—we shall see that it is obvious that as its sternal extremity is carried upward, it must also be thrown forward; so that the rib may be regarded as a radius moving on the vertebral joint as a centre, and causing the sternal attachment to describe an arc of a circle in the vertical plane of the body. Since all the ribs are oblique and connected in front to the sternum by the elastic costal cartilages, they must have a tendency to thrust the sternum forward, and so increase the antero-posterior diameter of the chest. By the *second* movement—that of the rotation of the rib on an axis corresponding with a line drawn from the head of the rib to the sternum—an elevation of the middle portion of the rib takes place, and consequently an increase in the transverse diameter of the chest. For the ribs not only slant downward and forward from their vertebral attachment, but they are also oblique in relation to their transverse plane—that is to say, their middle is on a lower level than either their vertebral or

FIG. 162.—Diagrams showing the axis of rotation of the ribs in the movements of respiration. The one axis of rotation corresponds with a line drawn through the two articulations which the rib forms with the spine (*a, b*), and the other with a line drawn from the head of the rib to the sternum (*A, B*). (From Kirke's *Handbook of Physiology*.)

sternal extremities. It results from this that when the ribs are raised, the centre portion is thrust outward, somewhat after the fashion in which the handle of a bucket is thrust away from the side when raised to a horizontal position, and the lateral diameter of the chest is increased (see Fig. 162). The mobility of the different ribs varies very much. The first rib is more fixed than the others, on account of the weight of the upper extremity and the strain of the ribs beneath; but on the freshly dissected thorax it moves as freely as the others. From the same causes the movement of the second rib is also not very extensive. In the other ribs this mobility increases successively down to the last two, which are very movable. The ribs are generally more movable in the female than in the male.

VII. Articulation of the Cartilages of the Ribs with the Sternum, etc. (Fig. 163).

The articulations of the cartilages of the true ribs with the sternum are arthrodial joints, with the exception of the first, in which the cartilage is almost always directly united with the sternum, and which must therefore be regarded as a synarthrodial articulation. The ligaments connecting them are—

Anterior Chondro-sternal.	Interarticular Chondro-sternal.
Posterior Chondro-sternal.	Anterior Chondro-xiphoid.
Capsular.	Posterior Chondro-xiphoid.

The **Anterior Chondro-sternal Ligament** is a broad and thin membranous band that radiates from the front of the inner extremity of the cartilages of the true ribs to the anterior surface of the sternum. It is composed of fasciculi which pass in different directions. The *superior fasciculi* ascend obliquely, the *inferior* pass obliquely downward, and the *middle fasciculi* horizontally. The superficial fibres of this ligament are the longest: they intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and with the tendinous fibres of origin of the Pectoralis major, forming a thick fibrous membrane which covers the surface of the sternum. This is more distinct at the lower than at the upper part.

The **Posterior Chondro-sternal Ligament**, less thick and distinct than the anterior, is composed of fibres which radiate from the posterior surface of the sternal end of the cartilages of the true ribs to the posterior surface of the sternum, becoming blended with the periosteum.

The **Capsular Ligament** surrounds the joints formed between the cartilages of the true ribs and the sternum. It is very thin, intimately blended with the anterior and posterior ligaments, and strengthened at the upper and lower part of the articulation by a few fibres which pass from the cartilage to the side of the sternum. These ligaments protect the synovial membranes.

The Interarticular Chondro-sternal Ligaments.—These are only found between the second and third costal cartilages and the sternum. The cartilage of the *second rib* is connected with the sternum by means of an *interarticular ligament* attached by one extremity to the cartilage of the second rib, and by the other extremity to the cartilage which unites the first and second pieces of the sternum. This articulation is provided with two synovial membranes. The cartilage of the third rib is connected with the sternum by means of an interarticular ligament which is attached by one extremity to the cartilage of the third rib, and by the other extremity to the point of junction of the second and third pieces of the sternum. This articulation is provided with two synovial membranes.

The Anterior Chondro-xiphoid.—This is a band of ligamentous fibres which connects the anterior surface of the seventh costal cartilage, and occasionally also that of the sixth, to the anterior surface of the ensiform appendix. It varies in length and breadth in different subjects.

The **Posterior Chondro-xiphoid** is a similar band of fibres on the internal or posterior surface, though less thick and distinct.

Synovial Membranes.—There is no synovial membrane between the first costal cartilage and the sternum, as this cartilage is directly continuous with the sternum. There are two synovial membranes, both in the articulation of the second and third costal cartilages to the sternum. There is generally one synovial membrane in each of the joints between the fourth, fifth, sixth, and seventh costal cartilages to the sternum; but it is sometimes absent in the sixth and seventh chondro-sternal joints. Thus there are *eight* synovial cavities on each side in the articulations between the costal cartilages of the true ribs and the sternum. After middle life the articular surfaces lose their polish, become roughened, and the synovial membranes appear to be wanting. In old age the articulations do not exist, the cartilages of most of the ribs becoming continuous with the sternum.

Actions.—The movements which are permitted in the chondro-sternal articulations are limited to elevation and depression, and these only to a slight extent.

Articulations of the Cartilages of the Ribs with each other (Interchondral) (Fig. 163).

The contiguous borders of the sixth, seventh, and eighth, and sometimes the ninth and tenth, costal cartilages articulate with each other by small, smooth, oblong-shaped facets. Each articulation is enclosed in a thin *capsular ligament* lined by *synovial membrane*, and strengthened externally and internally by ligamentous fibres (interchondral ligaments) which pass from one cartilage to the other. Sometimes the fifth costal cartilage, more rarely that of the ninth, articulates, by its lower border, with the adjoining cartilage by a small oval facet; more frequently they are connected together by a few ligamentous fibres. Occasionally the articular surfaces above mentioned are wanting.

Articulations of the Ribs with their Cartilages (Costo-chondral) (Fig. 163).

The outer extremity of each costal cartilage is received into a depression in the sternal end of the ribs, and the two are held together by the periosteum.

VIII. Articulations of the Sternum.

The first piece of the sternum is united to the second either by an amphiarthrodial joint—a single piece of true fibro-cartilage uniting the segments—or by a diarthrodial joint, in which each bone is clothed with a distinct lamina of cartilage, adherent on one side, free and lined with synovial membrane on the other. In the latter case the cartilage covering the gladiolus is continued without interruption on to the cartilages of the second ribs. Mr. Rivington has found the diarthrodial form of joint in about one-third of the specimens examined by him; Mr. Maisonneuve more frequently. It appears to be rare in childhood, and is formed, in Mr. Rivington's opinion, from the amphiarthrodial form by absorption. The diarthrodial joint seems to have no tendency to ossify at any age, while the amphiarthrodial is more liable to do so, and has been found ossified as early as thirty-four years of age. The two segments are further connected by an

Anterior Intersternal Ligament.

Posterior Intersternal Ligament.

The **Anterior Intersternal Ligament** consists of a layer of fibres, having a longitudinal direction; it blends with the fibres of the anterior chondro-sternal ligaments on both sides, and with the tendinous fibres of origin of the Pectoralis major. This ligament is rough, irregular, and much thicker below than above.

The **Posterior Intersternal Ligament** is disposed in a somewhat similar manner on the posterior surface of the articulation.

IX. Articulation of the Vertebral Column with the Pelvis.

The ligaments connecting the last lumbar vertebra with the sacrum are similar to those which connect the segments of the spine with each other—viz.: 1. The

FIG. 163.—Chondro-sternal, chondro-xiphoid, and interchondral articulations. Anterior view.

continuation downward of the anterior and posterior common ligaments. 2. The intervertebral substance connecting the flattened oval surfaces of the two bones and forming an amphiarthrodial joint. 3. Ligamenta subflava, connecting the arch of the last lumbar vertebra with the posterior border of the sacral canal. 4 Capsular ligaments connecting the articulating processes and forming a double arthrodia. 5. Inter- and supraspinous ligaments.

The two proper ligaments connecting the pelvis with the spine are the lumbo-sacral and ilio-lumbar.

The **Lumbo-sacral Ligament** (Fig. 164) is a short, thick, triangular fasciculus, which is connected above to the lower and front part of the transverse process

of the last lumbar vertebra, passes obliquely outward, and is attached below to the lateral surface of the base of the sacrum, becoming blended with the anterior sacro-iliac ligament. This ligament is in relation, in front, with the Psoas muscle.

The Ilio-lumbar Ligament (Fig. 164) passes horizontally outward from the

FIG. 164.—Articulations of pelvis and hip. Anterior view.

apex of the transverse process of the last lumbar vertebra to the crest of the ilium immediately in front of the sacro-iliac articulation. It is of a triangular form, thick and narrow internally, broad and thinner externally. It is in relation, in front, with the Psoas muscle; behind, with the muscles occupying the vertebral groove; above, with the Quadratus lumborum.

X. Articulations of the Pelvis.

The ligaments connecting the bones of the pelvis with each other may be divided into four groups: 1. Those connecting the sacrum and ilium. 2. Those passing between the sacrum and ischium. 3. Those connecting the sacrum and coccyx. 4. Those between the two pubic bones.

1. ARTICULATIONS OF THE SACRUM AND ILIUM.

The sacro-iliac articulation is an amphiarthrodial joint, formed between the lateral surfaces of the sacrum and ilium. The anterior or auricular portion of each articular surface is covered with a thin plate of cartilage, thicker on the sacrum than on the ilium. These are in close contact with each other, and to a certain extent united together by irregular patches of softer fibro-cartilage, and at their upper and posterior part by fine fibres of interosseous fibrous tissue. In a considerable part of their extent, especially in advanced life, they are not connected together, but are separated by a space containing a synovial-like fluid, and hence the joint presents the characters of a diarthrosis.

The ligaments connecting these surfaces are the anterior and posterior sacro-iliac.

The **Anterior Sacro-iliac Ligament** (Fig. 164) consists of numerous thin bands which connect the anterior surfaces of the sacrum and ilium.

The **Posterior Sacro-iliac** (Fig. 165) is a strong interosseous ligament, situated in a deep depression between the sacrum and ilium behind, and forming the chief bond of connection between those bones. It consists of numerous strong fasciculi which pass between the bones in various directions. Three of these are of large size: the *two superior*, nearly horizontal in direction, arise from the first and second transverse tubercles on the posterior surface of the sacrum, and are inserted into the rough, uneven surface at the posterior part of the inner surface of the ilium. The third fasciculus, oblique in direction, is attached by one extremity to the third transverse tubercle on the posterior surface of the sacrum, and by the other to the posterior superior spine of the ilium; it is sometimes called the *oblique sacro-iliac ligament*.

The position of the sacro-iliac joint is indicated by the posterior superior spine of the ilium. This process is immediately behind the centre of the articulation.

2. LIGAMENTS PASSING BETWEEN THE SACRUM AND ISCHIUM (Fig. 165).

The Great Sacro-sciatic (Posterior).

The Lesser Sacro-sciatic (Anterior).

The **Great or Posterior Sacro-sciatic Ligament** is situated at the lower and back part of the pelvis. It is flat, and triangular in form; narrower in the

FIG. 165.—Articulations of pelvis and hip. Posterior view

middle than at the extremities; attached by its broad base to the posterior inferior spine of the ilium, to the fourth and fifth transverse tubercles of the sacrum, and to the lower part of the lateral margin of that bone and the coccyx. Passing obliquely downward, outward, and forward, it becomes narrow and thick, and at its insertion into the inner margin of the tuberosity of the ischium it increases

in breadth, and is prolonged forward along the inner margin of the ramus, forming what is known as the *falciform ligament*. The free concave edge of this prolongation has attached to it the obturator fascia, with which it forms a kind of groove, protecting the internal pudic vessels and nerve. One of its surfaces is turned toward the perinæum, the other toward the Obturator internus muscle.

The *posterior surface* of this ligament gives origin, by its whole extent, to fibres of the Gluteus maximus. Its *anterior surface* is united to the lesser sacro-sciatic ligament. Its *external border* forms, above, the posterior boundary of the great sacro-sciatic foramen, and, below, the posterior boundary of the lesser sacro-sciatic foramen. Its *lower border* forms part of the boundary of the perinæum. It is pierced by the coccygeal branch of the sciatic artery and coccygeal nerve.

The **Lesser or Anterior Sacro-sciatic Ligament**, much shorter and smaller than the preceding, is thin, triangular in form, attached by its apex to the spine of the ischium, and internally, by its broad base, to the lateral margin of the sacrum and coccyx, anterior to the attachment of the great sacro-sciatic ligament, with which its fibres are intermingled.

It is in relation, *anteriorly*, with the Coccygeus muscle; *posteriorly*, it is covered by the great sacro-sciatic ligament and crossed by the internal pudic vessels and nerve. Its *superior border* forms the lower boundary of the great sacro-sciatic foramen; its *inferior border*, part of the lesser sacro-sciatic foramen.

These two ligaments convert the sacro-sciatic notches into foramina. The *superior* or *great sacro-sciatic foramen* is bounded, in front and above, by the

FIG. 166.—Side view of pelvis, showing the great and lesser sacro-sciatic ligaments.

posterior border of the os innominatum; behind, by the great sacro-sciatic ligament; and below, by the lesser sacro-sciatic ligament. It is partially filled up, in the recent state, by the Piriformis muscle, which passes through it. Above this muscle the gluteal vessels and superior gluteal nerve emerge from the pelvis, and, below it, the sciatic vessels and nerves, the internal pudic vessels and nerve, the inferior gluteal nerve, and the nerves to the obturator internus and quadratus femoris. The *inferior* or *lesser sacro-sciatic foramen* is bounded, in front, by the tuber ischii; above, by the spine and lesser sacro-sciatic ligament; behind, by the greater sacro-

sciatic ligament. It transmits the tendon of the Obturator internus muscle, its nerve, and the internal pudic vessels and nerve.

3. ARTICULATION OF THE SACRUM AND COCCYX.

This articulation is an amphiarthrodial joint, formed between the oval surface at the apex of the sacrum and the base of the coccyx. It is analogous to the joints between the bodies of the vertebræ, and is connected by similar ligaments. They are the

Anterior Sacro-coccygeal.
Posterior Sacro-coccygeal.

Lateral Sacro-coccygeal.
Interposed Fibro-cartilage.

Interarticular.

The **Anterior Sacro-coccygeal Ligament** consists of a few irregular fibres which descend from the anterior surface of the sacrum to the front of the coccyx, becoming blended with the periosteum.

The **Posterior Sacro-coccygeal Ligament** is a flat band of a pearly tint, which arises from the margin of the lower orifice of the sacral canal, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower and back part of the sacral canal. Its superficial fibres are much longer than the more deeply seated. This ligament is in relation, behind, with the *Gluteus maximus*.

The **Lateral Sacro-coccygeal Ligaments** connect the transverse processes of the coccyx to the lower lateral angles of the sacrum.

A **Fibro-cartilage** is interposed between the contiguous surfaces of the sacrum and coccyx; it differs from that interposed between the bodies of the vertebræ in being thinner, and its central part firmer in texture. It is somewhat thicker in front and behind than at the sides. Occasionally, a synovial membrane is found when the coccyx is freely movable, which is more especially the case during pregnancy.

The **Interarticular Ligaments** are thin bands of ligamentous tissue which connect the cornua of the two bones together.

The different segments of the coccyx are connected together by an extension downward of the anterior and posterior sacro-coccygeal ligaments, a thin annular disk of fibro-cartilage being interposed between each of the bones. In the adult male all the pieces become ossified, but in the female this does not commonly occur until a later period of life. The separate segments of the coccyx are first united, and at a more advanced age the joint between the sacrum and coccyx is obliterated.

Actions.—The movements which take place between the sacrum and coccyx, and between the different pieces of the latter bone, are forward and backward; they are very limited. Their extent increases during pregnancy.

4. ARTICULATION OF THE OSSA PUBIS (SYMPHYSIS PUBIS) (Fig. 167).

The articulation between the pubic bones is an amphiarthrodial joint, formed by the junction of the two oval articular surfaces of the ossa pubis. The ligaments of this articulation are the

Anterior Pubic.
Superior Pubic.

Posterior Pubic.
Subpubic.

Interpubic Disk.

The **Anterior Pubic Ligament** consists of several superimposed layers which pass across the front of the articulation. The superficial fibres pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the aponeurosis of the External oblique and the tendon of the Rectus muscles. The deep fibres pass transversely across the symphysis, and are blended with the fibro-cartilage.

The **Posterior Pubic Ligament** consists of a few thin, scattered fibres which unite the two pubic bones posteriorly.

The **Superior Pubic Ligament** is a band of fibres which connects together the two pubic bones superiorly.

The **Subpubic Ligament** is a thick, triangular arch of ligamentous fibres, connecting together the two pubic bones below and forming the upper boundary of the pubic arch. Above, it is blended with the interarticular fibro-cartilage; laterally it is united with the descending rami of the os pubis. Its fibres are closely connected and have an arched direction.

The **Interpubic Disk** consists of a disk of cartilage and fibro-cartilage connecting the surfaces of the pubic bones in front. Each of the two surfaces is covered by a thin layer of hyaline cartilage which is firmly connected to the bone by a series of nipple-like processes which accurately fit within corresponding depressions on the osseous surfaces. These opposed cartilaginous surfaces are connected together by an intermediate stratum of fibrous tissue and fibro-cartilage which varies in thickness in different subjects. It often contains a cavity in its centre, probably formed by the softening and absorption of the fibro-cartilage, since it rarely appears before the tenth year of life, and is not lined by synovial membrane. It is larger in the female than in the male, but it is very questionable whether it enlarges, as was formerly supposed, during pregnancy. It is most frequently limited to the upper and back part of the joint, but it occasionally reaches to the front, and may extend the entire length of the cartilage. This cavity may be easily demonstrated by making a vertical section of the symphysis pubis near its posterior surface (Fig. 167).

The **Obturator Ligament** is more properly regarded as analogous to the muscular fasciæ, with which it will be described.

FIG. 167.—Vertical section of the symphysis pubis. Made near its posterior surface.

ARTICULATIONS OF THE UPPER EXTREMITY.

The articulations of the upper extremity may be arranged in the following groups: I. Sterno-clavicular articulation. II. Acromio-clavicular articulation. III. Ligaments of the Scapula. IV. Shoulder-joint. V. Elbow-joint. VI. Radio-ulnar articulations. VII. Wrist-joint. VIII. Articulations of the Carpal Bones. IX. Carpo-metacarpal articulations. X. Metacarpo-phalangeal articulations. XI. Articulations of the Phalanges.

I. Sterno-clavicular Articulation (Fig. 168).

The **Sterno-clavicular** is regarded by most anatomists as an arthrodial joint, but Cruveilhier considers it to be an articulation by reciprocal reception. Probably the former opinion is the correct one, the varied movement which the joint enjoys being due to the interposition of an interarticular fibro-cartilage between the joint surfaces. The parts entering into its formation are the sternal end of the

clavicle, the upper and lateral part of the first piece of the sternum, and the cartilage of the first rib. The articular surface of the clavicle is much larger than

FIG. 168.—Sterno-clavicular articulation. Anterior view.

that of the sternum, and invested with a layer of cartilage¹ which is considerably thicker than that on the latter bone. The ligaments of this joint are the

Capsular.

Anterior Sterno-clavicular.

Posterior Sterno-clavicular.

Interclavicular.

Costo-clavicular (rhomboid).

Interarticular Fibro-cartilage.

The **Capsular Ligament** completely surrounds the articulation, consisting of fibres of varying degrees of thickness and strength. Those in front and behind are of considerable thickness, and form the anterior and posterior sterno-clavicular ligaments; but those above and below, especially in the latter situation, are thin and scanty, and partake more of the character of connective tissue than true fibrous tissue.

The **Anterior Sterno-clavicular Ligament** is a broad band of fibres which covers the anterior surface of the articulation, being attached, above, to the upper and front part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, below, to the upper and front part of the first piece of the sternum. This ligament is covered, in front, by the sternal portion of the Sterno-cleido-mastoid and the integument; behind, it is in relation with the interarticular fibro-cartilage and the two synovial membranes.

The **Posterior Sterno-clavicular Ligament** is a similar band of fibres which covers the posterior surface of the articulation, being attached, above, to the upper and back part of the inner extremity of the clavicle, and, passing obliquely downward and inward, is attached, below, to the upper and back part of the first piece of the sternum. It is in relation, in front, with the interarticular fibro-cartilage and synovial membranes; behind, with the Sterno-hyoid and Sterno-thyroid muscles.

The **Interclavicular Ligament** is a flattened band which varies considerably in form and size in different individuals; it passes in a curved direction from the upper part of the inner extremity of one clavicle to the other, and is also attached to the upper margin of the sternum. It is in relation, in front, with the integument; behind, with the Sterno-thyroid muscles.

The **Costo-clavicular Ligament (rhomboid)** is short, flat, and strong: it is of a rhomboid form, attached, below, to the upper and inner part of the cartilage of the first rib: it ascends obliquely backward and outward, and is attached, above,

¹ According to Bruch, the sternal end of the clavicle is covered by a tissue which is rather fibrous than cartilaginous in structure.

to the rhomboid depression on the under surface of the clavicle. It is in relation, in front, with the tendon of origin of the Subclavius; behind, with the subclavian vein.

The **Interarticular Fibro-cartilage** is a flat and nearly circular disk, interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, at its junction with the sternum; and by its circumference, to the anterior and posterior sterno-clavicular and interclavicular ligaments. It is thicker at the circumference, especially its upper and back part, than at its centre or below. It divides the joint into two cavities, each of which is furnished with a separate synovial membrane.

Of the two **Synovial Membranes** found in this articulation, one is reflected from the sternal end of the clavicle over the adjacent surface of the fibro-cartilage and cartilage of the first rib; the other is placed between the articular surface of the sternum and adjacent surface of the fibro-cartilage; the latter is the larger of the two.

Actions.—This articulation is the centre of the movements of the shoulder, and admits of a limited amount of motion in nearly every direction—upward, downward, backward, forward—as well as circumduction. When these movements take place in the joint, the clavicle in its motion carries the scapula with it, this bone gliding on the outer surface of the chest. This joint therefore forms the centre from which all movements of the supporting arch of the shoulder originate, and is the only point of articulation of this part of the skeleton with the trunk. “The movements attendant on elevation and depression of the shoulder take place between the clavicle and the interarticular fibro-cartilage, the bone rotating upon the ligament on an axis drawn from before backward through its own articular facet. When the shoulder is moved forward and backward, the clavicle, with the interarticular fibro-cartilage, rolls to and fro on the articular surface of the sternum, revolving, with a sliding movement, round an axis drawn nearly vertically through the sternum. In the circumduction of the shoulder, which is compounded of these two movements, the clavicle revolves upon the interarticular fibro-cartilage, and the latter, with the clavicle, rolls upon the sternum.”¹ Elevation of the clavicle is principally limited by the costo-clavicular ligament; depression, by the interclavicular. The muscles which *raise* the clavicle, as in shrugging the shoulders, are the upper fibres of the Trapezius, the Levator anguli scapulæ, the clavicular head of the Sterno-mastoid, assisted to a certain extent by the two Rhomboids, which pull the vertebral border of the Scapula backward and upward, and so raise the clavicle. The *depression* of the clavicle is principally effected by gravity, assisted by the Subclavius, Pectoralis minor, and lower fibres of the Trapezius. It is drawn *backward* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forward* by the Serratus magnus and Pectoralis minor.

Surface Form.—The position of the sterno-clavicular joint may be easily ascertained by feeling the enlarged sternal end of the collar-bone just external to the long, cord-like, sternal origin of the Sterno-mastoid muscle. If this muscle is relaxed by bending the head forward, a depression just internal to the end of the clavicle, and between it and the sternum, can be felt, indicating the exact position of the joint, which is subcutaneous. When the arm hangs by the side, the cavity of the joint is V-shaped. If the arm is raised, the bones become more closely approximated, and the cavity becomes a mere slit.

Surgical Anatomy.—The strength of this joint mainly depends upon its ligaments, and it is to this, and to the fact that the force of the blow is generally transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the bone is generally broken rather than displaced. When dislocation does occur, the course which the displaced bone takes depends more upon the direction in which the violence is applied than upon the anatomical construction of the joint; it may be either forward, backward, or upward. The chief point worthy of note, as regards the construction of the joint, in regard to dislocations, is the fact that, owing to the shape of the articular surfaces being so little adapted to each other, and that the strength of the joint mainly depends upon the ligaments, the displacement when reduced is very liable to recur, and hence it is extremely difficult to keep the end of the bone in its proper place.

¹ Humphry, *On the Human Skeleton*, p. 402.

II. Acromio-clavicular Articulation (Fig. 169).

The **Acromio-clavicular** is an arthrodial joint formed between the outer extremity of the clavicle and the inner margin of the acromion process of the scapula. Its ligaments are the

Superior Acromio-clavicular.	Coraco-clavicular	{ Trapezoid and Conoid.
Inferior Acromio-clavicular.		
Interarticular Fibro-cartilage.		

The **Superior Acromio-clavicular Ligament** is a quadrilateral band which covers the superior part of the articulation, extending between the upper part of the outer end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres which interlace with the aponeurosis of the Trapezius and Deltoid muscles; below, it is in contact with the inter-articular fibro-cartilage (when it exists) and the synovial membranes.

The **Inferior Acromio-clavicular Ligament**, somewhat thinner than the preceding, covers the under part of the articulation, and is attached to the adjoining surfaces of the two bones. It is in relation, above, with the synovial membranes, and in rare cases with the interarticular fibro-cartilage; below, with the tendon

FIG. 169.—The left shoulder-joint, scapulo-clavicular articulations, and proper ligaments of scapula.

of the Supraspinatus. These two ligaments are continuous with each other in front and behind, and form a complete capsule round the joint.

The **Interarticular Fibro-cartilage** is frequently absent in this articulation. When it exists it generally only partially separates the articular surfaces, and occupies the upper part of the articulation. More rarely it completely separates the joint into two cavities.

The Synovial Membrane.—There is usually only one synovial membrane in

this articulation, but when a complete interarticular fibro-cartilage exists there are two synovial membranes.

The **Coraco-clavicular Ligament** serves to connect the clavicle with the coracoid process of the scapula. It does not properly belong to this articulation, but as it forms a most efficient means in retaining the clavicle in contact with the acromial process, it is usually described with it. It consists of two fasciculi, called the *trapezoid* and *conoid ligaments*.

The *Trapezoid Ligament*, the anterior and external fasciculus, is broad, thin, and quadrilateral; it is placed obliquely between the coracoid process and the clavicle. It is attached, below, to the upper surface of the coracoid process; above, to the oblique line on the under surface of the clavicle. Its anterior border is free; its posterior border is joined with the conoid ligament, the two forming by their junction a projecting angle.

The *Conoid Ligament*, the posterior and internal fasciculus, is a dense band of fibres, conical in form, the base being directed upward, the summit downward. It is attached by its apex to a rough impression at the base of the coracoid process, internal to the preceding; above, by its expanded base, to the conoid tubercle on the under surface of the clavicle, and to a line proceeding internally from it for half an inch. These ligaments are in relation, in front, with the Subclavius and Deltoid; behind, with the Trapezius. They serve to limit rotation of the scapula, the Trapezoid limiting rotation forward, and the Conoid backward.

Actions.—The movements of this articulation are of two kinds: 1. A gliding motion of the articular end of the clavicle on the acromion. 2. Rotation of the scapula forward and backward upon the clavicle, the extent of this rotation being limited by the two portions of the coraco-clavicular ligament.

The acromio-clavicular joint has important functions in the movements of the upper extremity. It has been well pointed out by Sir George Humphry that if there had been no joint between the clavicle and scapula the circular movement of the scapula on the ribs (as in throwing both shoulders backward or forward) would have been attended with a greater alteration in the direction of the shoulder than is consistent with the free use of the arm in such position, and it would have been impossible to give a blow straight forward with the full force of the arm; that is to say, with the combined force of the scapula, arm, and forearm. "This joint," as he happily says, "is so adjusted as to enable either bone to turn in a hinge-like manner upon a vertical axis drawn through the other, and it permits the surfaces of the scapula, like the baskets in a roundabout swing, to look the same way in every position or nearly so." Again, when the whole arch formed by the clavicle and scapula rises and falls (in elevation or depression of the shoulders), the joint between these two bones enables the scapula still to maintain its lower part in contact with the ribs.

Surface Form.—The position of the acromio-clavicular joint can generally be ascertained by the slightly enlarged extremity of the outer end of the clavicle, which causes it to project above the level of the acromion process of the scapula. Sometimes this enlargement is so considerable as to form a rounded eminence, which is easily to be felt. The joint lies in the plane of a vertical line passing up the middle of the front of the arm.

Surgical Anatomy.—Owing to the slanting shape of the articular surfaces of this joint, dislocation generally occurs downward; that is to say, the acromion process of the scapula is dislocated under the outer end of the clavicle; but dislocations in the opposite direction have been described. The displacement is often incomplete, on account of the strong coraco-clavicular ligaments, which remain untorso. The same difficulty exists, as in the sterno-clavicular dislocation, in maintaining the ends of the bone in position after reduction.

III. Proper Ligaments of the Scapula (Fig. 169).

The proper ligaments of the scapula are the

Coraco-acromial.

Transverse.

The **Coraco-acromial Ligament** is a strong triangular band, extending between the coracoid and acromial processes. It is attached, by its apex, to the summit

of the acromion just in front of the articular surface for the clavicle, and by its broad base to the whole length of the outer border of the coracoid process. Its posterior fibres are directed inward, its anterior fibres forward and inward. This ligament completes the vault formed by the coracoid and acromion processes for the protection of the head of the humerus. It is in relation, above, with the clavicle and under surface of the Deltoid; below, with the tendon of the Supraspinatus muscle, a bursa being interposed. Its outer border is continuous with a dense lamina that passes beneath the Deltoid upon the tendons of the Supra- and Infraspinatus muscles. This ligament is sometimes described as consisting of two marginal bands and a thinner intervening portion, the two bands being attached respectively to the apex and base of the coracoid process, and joining together at their attachment into the acromion process. When the Pectoralis minor is inserted, as sometimes is the case, into the capsule of the shoulder-joint instead of into the coracoid process, it passes between these two bands, and the intervening portion is then deficient.

The Transverse or Coracoid (*suprascapular*) Ligament converts the suprascapular notch into a foramen. It is a thin and flat fasciculus, narrower at the middle than at the extremities, attached by one end to the base of the coracoid process, and by the other to the inner extremity of the scapular notch. The suprascapular nerve passes through the foramen; the suprascapular vessels pass over the ligament.

An additional ligament (the *spino-glenoid*) is sometimes found on the scapula, stretching from the outer border of the spine to the margin of the glenoid cavity. When present, it forms an arch under which the suprascapular vessels and nerve pass as they enter the infraspinous fossa.

FIG. 170. — Vertical sections through the shoulder-joint, the arm being vertical and horizontal. (After Henle.)

Movements of Scapula.—The scapula is capable of being moved upward and downward, forward and backward, or, by a combination of these movements, circumducted on the wall of the chest. The muscles which *raise* the scapula are the upper fibres of the Trapezius, the Levator anguli scapulae, and the two Rhomboids; those which *depress* it are the lower fibres of the Trapezius, the Pectoralis minor, and, through the clavicle, the Subclavius. The scapula is drawn *backward* by the Rhomboids and the middle and lower fibres of the Trapezius, and *forward* by the Serratus magnus and Pectoralis minor, assisted, when the arm is fixed, by the Pectoralis major. The mobility of the scapula is very considerable, and greatly assists the movements of the arm at the shoulder-joint. Thus, in raising the arm from the side the Deltoid and Supraspinatus can only lift it to a right

angle with the trunk, the further elevation of the limb being effected by the Trapezius and Serratus magnus moving the scapula on the wall of the chest. This mobility is of special importance in ankylosis of the shoulder-joint, the movements of this bone compensating to a very great extent for the immobility of the joint.

IV. Shoulder-joint (Fig. 169).

The **Shoulder** is an enarthrodial or ball-and-socket joint. The bones entering into its formation are the large globular head of the humerus, which is received into the shallow glenoid cavity of the scapula—an arrangement which permits of very considerable movement, whilst the joint itself is protected against displacement by the tendons which surround it and by atmospheric pressure. The ligaments do not maintain the joint surfaces in apposition, because when they alone remain the humerus can be separated to a considerable extent from the glenoid cavity; their use, therefore, is to limit the amount of movement. Above, the joint is protected by an arched vault, formed by the under surface of the coracoid and acromion processes, and the coraco-acromial ligament. The articular surfaces are covered by a layer of cartilage: that on the head of the humerus is thicker at the centre than at the circumference, the reverse being the case in the glenoid cavity. The ligaments of the shoulder are the

Capsular.
Coraco-humeral.

Transverse humeral.
Glenoid.¹

The **Capsular Ligament** completely encircles the articulation, being attached, above, to the circumference of the glenoid cavity beyond the glenoid ligament; below, to the anatomical neck of the humerus, approaching nearer to the articular cartilage above than in the rest of its extent. It is thicker above and below than elsewhere, and is remarkably loose and lax, and much larger and longer than is necessary to keep the bones in contact, allowing them to be separated from each other more than an inch—an evident provision for that extreme freedom of movement which is peculiar to this articulation. Its superficial surface is strengthened, above, by the Supraspinatus; below, by the long head of the Triceps; behind, by the tendons of the Infraspinatus and Teres minor; and in front, by the tendon of the Subscapularis. The capsular ligament usually presents three openings; one anteriorly, below the coracoid process, establishes a communication between the synovial membrane of the joint and a bursa beneath the tendon of the Subscapularis muscle. The second, which is not constant, is at the posterior part, where a communication sometimes exists between the joint and a bursal sac belonging to the Infraspinatus muscle. The third is seen between the two tuberosities, for the passage of the long tendon of the Biceps muscle.

The **Coraco-humeral** is a broad band which strengthens the upper part of the capsular ligament. It arises from the outer border of the coracoid process, and passes obliquely downward and outward to the front of the great tuberosity of the humerus, being blended with the tendon of the Supraspinatus muscle. This ligament is intimately united to the capsular in the greater part of its extent.

Supplemental Bands of the Capsular Ligament.—In addition to the coraco-humeral ligament, the capsular ligament is strengthened by supplemental bands in the interior of the joint. One of these bands is situated on the inner side of the joint, and passes from the inner edge of the glenoid cavity to the lower part of the lesser tuberosity of the humerus. This is sometimes known as *Flood's ligament*, and is supposed to correspond with the ligamentum teres of the hip-joint. A second of these bands is situated at the lower part of the joint, and passes from the under edge of the glenoid cavity to the under part of the neck of the humerus, and is known as *Schlemm's ligament*. A third, called the *gleno-humeral ligament*, is situated at the upper part of the joint, and projects into its interior, so that it can

¹ The long tendon of origin of the Biceps muscle also acts as one of the ligaments of this joint. See the observations on p. 222 on the function of the muscles passing over more than one joint.

be seen only when the capsule is opened. It is attached above to the apex of the glenoid cavity, close to the root of the coracoid process, and, passing downward along the inner edge of the tendon of the Biceps, is attached below to the lesser tuberosity of the humerus, where it forms the inner boundary of the upper part of the bicipital groove. It is a thin, ribbon-like band, occasionally quite free from the capsule.

The Transverse Humeral Ligament.—This is a broad band of fibrous tissue passing from the lesser to the greater tuberosity of the humerus, and always limited to that portion of the bone which lies above the epiphyseal line. It converts the bicipital groove into an osseo-aponeurotic canal, and is the analogue of the strong process of bone which connects the summits of the two tuberosities in the musk ox.

The Glenoid Ligament is a fibro-cartilaginous rim, attached round the margin of the glenoid cavity. It is triangular on section, the thickest portion being fixed to the circumference of the cavity, the free edge being thin and sharp. It is continuous above with the long tendon of the Biceps muscle, which bifurcates at the upper part of the cavity into two fasciculi, and becomes continuous with the fibrous tissue of the glenoid ligament. This ligament deepens the cavity for articulation, and protects the edges of the bone. It is lined by the synovial membrane.

The Synovial Membrane is reflected from the margin of the glenoid cavity over the fibro-cartilaginous rim surrounding it: it is then reflected over the internal surface of the capsular ligament, covers the lower part and sides of the anatomical neck of the humerus as far as the cartilage covering the head of the bone. The long tendon of the Biceps muscle which passes through the capsular ligament is enclosed in a tubular sheath of synovial membrane, which is reflected upon it at the point where it perforates the capsule, and is continued around it as far as the summit of the glenoid cavity. The tendon of the Biceps is thus enabled to transmit the articulation, but it is not contained in the interior of the synovial cavity. The synovial membrane communicates with a large bursal sac beneath the tendon of the Subscapularis by an opening at the inner side of the capsular ligament; it also occasionally communicates with another bursal sac, beneath the tendon of the Infraspinatus, through an orifice at its posterior part. A third bursal sac, which does not communicate with the joint, is placed between the under surface of the Deltoid and the outer surface of the capsule.

The Muscles in relation with the joint are, above, the Supraspinatus; below, the long head of the Triceps; in front, the Subscapularis; behind, the Infraspinatus and Teres minor; within, the long tendon of the Biceps. The Deltoid is placed most externally, and covers the articulation on its outer side, as well as in front and behind.

The Arteries supplying the joint are articular branches of the anterior and posterior circumflex, and suprascapular.

The Nerves are derived from the circumflex and suprascapular.

Actions.—The shoulder-joint is capable of movement in every direction, forward, backward, abduction, adduction, circumduction, and rotation. The humerus is drawn *forward* by the Pectoralis major, anterior fibres of the Deltoid, Coracobrachialis, and by the Biceps when the forearm is flexed; *backward*, by the Latissimus dorsi, Teres major, posterior fibres of the Deltoid, and by the Triceps when the forearm is extended; it is *abducted* (elevated) by the Deltoid and Supraspinatus; it is *adducted* (depressed) by the Subscapularis, Pectoralis major, Latissimus dorsi, and Teres major; it is *rotated outward* by the Infraspinatus and Teres minor; and it is *rotated inward* by the Subscapularis, Latissimus dorsi, Teres major, and Pectoralis major.

The most striking peculiarities in this joint are: 1. The large size of the head of the humerus in comparison with the depth of the glenoid cavity, even when supplemented by the glenoid ligament. 2. The looseness of the capsule of the

joint. 3. The intimate connection of the capsule with the muscles attached to the head of the humerus. 4. The peculiar relation of the biceps tendon to the joint.

It is in consequence of the relative size of the two articular surfaces that the joint enjoys such free movement in every possible direction. When these movements of the arm are arrested in the shoulder-joint by the contact of the bony surfaces and by the tension of the corresponding fibres of the capsule, together with that of the muscles acting as accessory ligaments, they can be carried considerably farther by the movements of the scapula, involving, of course, motion at the acromio- and sterno-clavicular joints. These joints are therefore to be regarded as accessory structures to the shoulder-joint.¹ The extent of these movements of the scapula is very considerable, especially in extreme elevation of the arm, which movement is best accomplished when the arm is thrown somewhat forward and outward, because the margin of the head of the humerus is by no means a true circle; its greatest diameter is from the bicipital groove downward, inward, and backward, and the greatest elevation of the arm can be obtained by rolling its articular surface in the direction of the measurement. The great width of the central portion of the humeral head also allows of very free horizontal movement when the arm is raised to a right angle, in which movement the arch formed by the acromion, the coracoid process, and the coraco-acromial ligament constitutes a sort of supplemental articular cavity for the head of the bone.

The looseness of the capsule is so great that the arm will fall about an inch from the scapula when the muscles are dissected from the capsular ligament and an opening made in it to remove the atmospheric pressure. The movements of the joint, therefore, are not regulated by the capsule so much as by the surrounding muscles and by the pressure of the atmosphere—an arrangement which “renders the movements of the joint much more easy than they would otherwise have been, and permits a swinging, pendulum-like vibration of the limb when the muscles are at rest” (Humphry). The fact, also, that in all ordinary positions of the joint the capsule is not put on the stretch enables the arm to move freely in all directions. Extreme movements are checked by the tension of appropriate portions of the capsule, as well as by the interlocking of the bones. Thus it is said that “abduction is checked by the contact of the great tuberosity with the upper edge of the glenoid cavity, adduction by the tension of the coraco-humeral ligament” (Beaunis et Bouchard). Cleland² maintains that the limitations of movement at the shoulder-joint are due to the structure of the joint itself, the glenoid ligament fitting, in different positions of the elevated arm, into the anatomical neck of the humerus.

Cathcart³ has pointed out that in abducting the arm and raising it above the head, the scapula rotates throughout the whole movement with the exception of a short space at the beginning and at the end; that the humerus moves on the scapula not only from the hanging to the horizontal position, but also in passing upward as it approaches the vertical above; that the clavicle moves not only during the second half of the movement but in the first as well, though to a less extent—*i. e.*, the scapula and clavicle are concerned in the first stage as well as in the second; and that the humerus is partly involved in the second as well as chiefly in the first.

The intimate union of the tendons of the four short muscles with the capsule converts these muscles into elastic and spontaneously acting ligaments of the joint, and it is regarded as being also intended to prevent the folds into which all portions of the capsule would alternately fall in the varying positions of the joint from being driven between the bones by the pressure of the atmosphere.

The peculiar relations of the Biceps tendon to the shoulder-joint appear to subserve various purposes. In the first place, by its connection with both the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic ligament in all positions, in the manner previously adverted to.⁴ Next, it strengthens the upper part of the articular cavity, and prevents the head of the

¹ See p. 249.

² *Journal of Anatomy and Physiology*, vol. xviii., 1884.

³ *Ibid.*

⁴ See p. 222.

humerus from being pressed up against the acromion process, when the Deltoid contracts, instead of forming the centre of motion in the glenoid cavity. By its passage along the bicipital groove it assists in rendering the head of the humerus steady in the various movements of the arm. When the arm is raised from the side it assists the Supra- and Infraspinatus in rotating the head of the humerus in the glenoid cavity. It also holds the head of the bone firmly in contact with the glenoid cavity, and prevents its slipping over its lower edge, or being displaced by the action of the Latissimus dorsi and Pectoralis major, as in climbing and many other movements.

Surface Form.—The direction and position of the shoulder-joint may be indicated by a line drawn from the middle of the coraco-acromial ligament, in a curved direction, with its convexity inward, to the innermost part of that portion of the head of the humerus which can be felt in the axilla when the arm is forcibly abducted from the side. When the arm hangs by the side, not more than one-third of the head of the bone is in contact with the glenoid cavity, and three-quarters of its circumference is in front of a vertical line drawn from the anterior border of the acromion process.

Surgical Anatomy.—Owing to the construction of the shoulder-joint and the freedom of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint in the body. Dislocation occurs when the arm is abducted, and when, therefore, the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. The head of the bone does not usually remain in this situation, but generally assumes some other position, which varies according to the direction and amount of force producing the dislocation and the relative strength of the muscles in front and behind the joint. In consequence of the muscles at the back being stronger than those in front, and especially on account of the long head of the Triceps preventing the bone passing backward, dislocation forward is much more common than backward. The most frequent position which the head of the humerus ultimately assumes is on the front of the neck of the scapula, beneath the coracoid process, and hence named subcoracoid dislocation. Occasionally, in consequence probably of a greater amount of force being brought to bear on the limb, the head is driven farther inward, and rests on the upper part of the front of the chest, beneath the clavicle (subclavicular). Sometimes it remains in the position in which it was primarily displaced, resting on the axillary border of the scapula (subglenoid), and rarely it passes backward and remains in the infraspinatus fossa, beneath the spine (subspinous).

The shoulder-joint is sometimes the seat of all those inflammatory affections, both acute and chronic, which attack joints, though perhaps less frequently than some other joints of equal size and importance. Acute synovitis may result from injury, rheumatism, or pyæmia, or may follow secondarily on the so-called acute epiphysitis of infants. It is attended with effusion into the joint, and when this occurs the capsule is evenly distended and the contour of the joint rounded. Special projections may occur at the site of the openings in the capsular ligament. Thus a swelling may appear just in front of the joint, internal to the lesser tuberosity, from effusion into the bursa beneath the Subscapularis muscle; or, again, a swelling which is sometimes bilobed may be seen in the interval between the Deltoid and Pectoralis major muscles, from effusion into the diverticulum, which runs down the bicipital groove with the tendon of the biceps. The effusion into the synovial membrane can be best ascertained by examination from the axilla, where a soft, elastic, fluctuating swelling can usually be felt.

Tubercular arthritis not unfrequently attacks the shoulder-joint, and may lead to total destruction of the articulation, when ankylosis may result or long-protracted suppuration may necessitate excision. This joint is also one of those which is most liable to be the seat of osteoarthritis, and may also be affected in gout and rheumatism; or in locomotor ataxy, when it becomes the seat of Charcot's disease.

Excision of the shoulder-joint may be required in cases of arthritis (especially the tubercular form) which have gone on to destruction of the articulation; in compound dislocations and fractures, particularly those arising from gunshot injuries, in which there has been extensive injury to the head of the bone; in some cases of old unreduced dislocation, where there is much pain; and possibly in some few cases of growth connected with the upper end of the bone. The operation is best performed by making an incision from the middle of the coraco-acromial ligament down the arm for about three inches: this will expose the bicipital groove and the tendon of the Biceps, which may be either divided or hooked out of the way, according as to whether it is implicated in the disease or not. The capsule is then freely opened, and the muscles attached to the greater and lesser tuberosities of the humerus divided. The head of the bone can then be thrust out of the wound and sawn off, or divided with a narrow saw *in situ* and subsequently removed. The section should be made, if possible, just below the articular surface, so as to leave the bone as long as possible. The glenoid cavity must then be examined, and gouged if carious.

V. Elbow-joint (Figs. 171, 172).

The **Elbow** is a *ginglymus* or hinge-joint. The bones entering into its formation are the trochlear of the humerus, which is received into the greater sigmoid cavity of the ulna, and admits of the movements peculiar to this joint—viz. flexion and extension; whilst the lesser, or radial, head of the humerus articulates with the cup-shaped depression on the head of the radius; the circumference of the head of the radius articulates with the lesser sigmoid cavity of the ulna, allowing of the movement of rotation of the radius on the ulna, the chief action of the superior radio-ulnar articulation. The articular surfaces are covered with a thin layer of cartilage, and connected together by a capsular ligament of unequal thickness, being especially thickened on its two sides and, to a less extent, in front and behind. These thickened portions are usually described as distinct ligaments under the following names:

Anterior.
Posterior.

Internal Lateral.
External Lateral.

The orbicular ligament of the upper radio-ulnar articulation must also be reckoned among the ligaments of the elbow.

The **Anterior Ligament** (Fig. 171) is a broad and thin fibrous layer which covers the anterior surface of the joint. It is attached to the front of the internal condyle and to the front of the humerus immediately above the coronoid and radial fossæ; below,

FIG. 171.—Left elbow-joint, showing anterior and internal ligaments.

FIG. 172.—Left elbow-joint, showing posterior and external ligaments.

to the anterior surface of the coronoid process of the ulna and orbicular ligament, being continuous on each side with the lateral ligaments. Its superficial

fibres pass obliquely from the inner condyle of the humerus outward to the orbicular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but mainly inserted into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. This ligament is in relation, in front, with the *Brachialis anticus*, except at its outermost part; behind, with the synovial membrane.

The **Posterior Ligament** (Fig. 172) is a thin and loose membranous fold, attached, above, to the lower end of the humerus, above and at the sides of the olecranon fossa; below, to the groove on the upper and outer surfaces of the olecranon. The superficial or transverse fibres pass between the adjacent margins of the olecranon fossa. The deeper portion consists of vertical fibres, some of which, thin and weak, pass from the upper part of the olecranon fossa to the margin of the olecranon; others, thicker and stronger, pass from the back of the capitellum of the humerus to the posterior border of the lesser sigmoid cavity of the ulna. This ligament is in relation, behind, with the tendon of the *Triceps* and the *Anconeus*; in front, with the synovial membrane.

The **Internal Lateral Ligament** (Fig. 171) is a thick triangular band consisting of two portions, an anterior and posterior, united by a thinner intermediate portion. The *anterior portion*, directed obliquely forward, is attached, above, by its apex, to the front part of the internal condyle of the humerus; and, below, by its broad base, to the inner margin of the coronoid process. The *posterior portion*, also of triangular form, is attached, above, by its apex, to the lower and back part of the internal condyle; below, to the inner margin of the olecranon. Between these two bands a few intermediate fibres descend from the internal condyle to blend with a transverse band of ligamentous tissue which bridges across the notch between the olecranon and coronoid processes. This ligament is in relation, internally, with the *Triceps* and *Flexor carpi ulnaris* muscles and the ulnar nerve, and gives origin to part of the *Flexor sublimis digitorum*.

The **External Lateral Ligament** (Fig. 172) is a short and narrow fibrous band, less distinct than the internal, attached, above, to a depression below the external condyle of the humerus; below, to the orbicular ligament, some of its most posterior fibres passing over that ligament, to be inserted into the outer margin of the ulna. This ligament is intimately blended with the tendon of origin of the *Supinator brevis* muscle.

The **Synovial Membrane** is very extensive. It covers the margin of the articular surface of the humerus, and lines the coronoid and olecranon fossæ on that bone; from these points it is reflected over the anterior, posterior, and lateral ligaments, and forms a pouch between the lesser sigmoid cavity, the internal surface of the orbicular ligament, and the circumference of the head of the radius. Projecting into the cavity is a crescentic fold of synovial membrane, between the radius and ulna, suggesting the division of the joint into two: one the humero-radial, the other the humero-ulnar.

Between the capsular ligament and the synovial membrane are three masses of fat; one, the largest, above the olecranon fossa, which is pressed into the fossa by the *triceps* during flexion; a second, over the coronoid fossa; and a third, over the radial fossa. These are pressed into their respective fossæ during extension.

The **Muscles** in relation with the joint are, in front, the *Brachialis anticus*; behind, the *Triceps* and *Anconeus*; externally, the *Supinator brevis* and the common tendon of origin of the *Extensor* muscles; internally, the common tendon of origin of the *Flexor* muscles, and the *Flexor carpi ulnaris*, with the ulnar nerve (Fig. 173).

The **Arteries** supplying the joint are derived from the anastomosis between the superior profunda, inferior profunda, and anastomotica magna arteries, branches of the brachial, with the anterior, posterior, and interosseous recurrent branches of the ulnar and the recurrent branch of the radial. These vessels form a complete chain of inosculation around the joint.

The *Nerves* are derived from the ulnar as it passes between the internal condyle and the olecranon; a filament from the musculo-cutaneous (Rüdinger), and two from the median (Macalister).

Actions.—The elbow-joint comprises three different portions—viz., the joint between the ulna and humerus, that between the head of the radius and the humerus, and the superior radio-ulnar articulation, described below. All these articular surfaces are invested by a common synovial membrane, and the movements of the whole joint should be studied together. The combination of the movements of flexion and extension of the forearm with those of pronation and supination of the hand, which is ensured by the two being performed at the same joint, is essential to the accuracy of the various minute movements of the hand.

The portion of the joint between the ulna and humerus is a simple hinge-joint, and allows of movements of flexion and extension only. Owing to the obliquity of the trochlear surface of the humerus, this movement does not take place in a straight line; so that when the forearm is extended and supinated the axis of the arm and forearm is not in the same line, but the one portion of the limb forms an angle with the others, and the hand, with the forearm, is directed outward. During flexion, on the other hand, the forearm and the hand tend to approach the middle line of the body, and thus enable the hand to be easily carried to the face. The shape of the articular surface of the humerus, with its prominences and depressions accurately adapted to the opposing surfaces of the olecranon, prevents any lateral movement. *Flexion* is produced by the action of the Biceps and Brachialis anticus, assisted by the muscles arising from the internal condyle of the humerus and the Supinator longus; *extension*, by the Triceps and Anconeus, assisted by the extensors of the wrist and by the Extensor communis digitorum and Extensor minimi digiti.

The joint between the head of the radius and the capitellum or radial head of the humerus is an arthrodial joint. The bony surfaces would of themselves constitute an enarthrosis, and allow of movement in all directions were it not for the orbicular ligament by which the head of the radius is bound down firmly to the sigmoid cavity of the ulna, and which prevents any separation of the two bones laterally. It is to the same ligament that the head of the radius owes its security from dislocation, which would otherwise constantly occur as a consequence of the shallowness of the cup-like surface on the head of the radius. In fact, but for this ligament the tendon of the biceps would be liable to pull the head of the radius out of the joint.¹ In complete extension the head of the radius glides so far back on the outer condyle that its edge is plainly felt at the back of the articulation. Flexion and extension of the elbow-joint are limited by the tension of the structures on the front and back of the joint, the limitation of flexion being also aided by the soft structures of the arm and forearm coming in contact.

In combination with any position of flexion or extension the head of the radius

FIG. 173.—Sagittal section of the right elbow-joint, taken somewhat obliquely and seen from the radial aspect. (After Braune.)

¹ Humphry, *op. cit.*, p. 419.

can be rotated in the upper radio-ulnar joint, carrying the hand with it. The hand is directly articulated to the lower surface of the radius only, and the concave or sigmoid surface on the lower end of the radius travels round the lower end of the ulna. The latter bone is excluded from the wrist-joint (as will be seen in the sequel) by the interarticular fibro-cartilage. Thus, rotation of the head of the radius round an axis which passes through the centre of the radial head of the humerus imparts circular movement to the hand through a very considerable arc.

Surface Form.—If the forearm be slightly flexed on the arm, a curved crease or fold with its convexity downward may be seen running across the front of the elbow, extending from one condyle to the other. The centre of this fold is some slight distance above the line of the joint. The position of the radio-humeral portion of the joint can be at once ascertained by feeling for a slight groove or depression between the head of the radius and the capitellum of the humerus at the back of the articulation.

Surgical Anatomy.—From the great breadth of the joint, and the manner in which the articular surfaces are interlocked, and also on account of the strong lateral ligaments and the support which the joint derives from the mass of muscles attached to each condyle of the humerus, lateral displacement of the bones is very uncommon, whereas antero-posterior dislocation, on account of the shortness of the antero-posterior diameter, the weakness of the anterior and posterior ligaments, and the want of support of muscles, much more frequently takes place, dislocation backward taking place when the forearm is in a position of extension, and forward when in a position of flexion. For, in the former position, that of extension, the coronoid process is not interlocked into the coronoid fossa, and loses its grip to a certain extent, whereas the olecranon process is in the olecranon fossa, and entirely prevents displacement forward. On the other hand, during flexion, the coronoid process is in the coronoid fossa, and prevents dislocation backward, while the olecranon loses its grip and is not so efficient, as during extension, in preventing a forward displacement. When lateral dislocation does take place, it is generally incomplete.

Dislocation of the elbow-joint is of common occurrence in children, far more common than dislocation of any other articulation, for, as a rule, fracture of a bone more frequently takes place, under the application of any severe violence, in young persons than dislocation. In lesions of this joint there is often very great difficulty in ascertaining the exact nature of the injury.

The elbow-joint is occasionally the seat of acute synovitis. The synovial membrane then becomes distended with fluid, the bulging showing itself principally around the olecranon process; that is to say, on its inner and outer sides and above, in consequence of the laxness of the posterior ligament. Occasionally a well-marked, triangular projection may be seen on the outer side of the olecranon, from bulging of the synovial membrane beneath the Anconeus muscle. Again, there is often some swelling just above the head of the radius, in the line of the radio-humeral joint. There is generally not much swelling at the front of the joint, though sometimes deep-seated fulness beneath the Brachialis anticus may be noted. When suppuration occurs the abscess usually points at one or other border of the Triceps muscle; occasionally the pus discharges itself in front, near the insertion of the Brachialis anticus muscle. Chronic synovitis, usually of tubercular origin, is of common occurrence in the elbow-joint: under these circumstances the forearm tends to assume the position of semi-flexion which is that of greatest ease and relaxation of ligaments. It should be borne in mind that should ankylosis occur in this or the extended position, the limb will not be nearly so useful as if ankylosed in a position of rather less than a right angle. Loose cartilages are sometimes met with in the elbow-joint, not so commonly, however, as in the knee; nor do they, as a rule, give rise to such urgent symptoms, and rarely require operative interference. The elbow-joint is also sometimes affected with osteo-arthritis, but this affection is less common in this articulation than in some other of the larger joints.

Excision of the elbow is principally required for three conditions: viz. tubercular arthritis, injury and its results, and faulty ankylosis; but may be necessary for some other rarer conditions, such as disorganizing arthritis after pyæmia, unreduced dislocations, and osteo-arthritis. The results of the operation are, as a rule, more favorable than those of excision of any other joint, and it is one, therefore, that the surgeon should never hesitate to perform, especially in the first three of the conditions mentioned above. The operation is best performed by a single vertical incision down the back of the joint, a transverse incision, over the outer condyle, being added if the parts are much thickened and fixed. A straight incision is made about four inches long, the mid-point of which is on a level with and a little to the inner side of the tip of the olecranon. This incision is made down to the bone, through the substance of the Triceps muscle. The operator with the point of his knife, and guarding the soft parts with his thumb-nail, separates them from the bone. In doing this there are two structures which he should carefully avoid: the ulnar nerve, which lies parallel to his incision, but a little internal, as it courses down between the internal condyle and the olecranon process, and the prolongation of the Triceps into the deep fascia of the forearm over the Anconeus muscle. Having cleared the bones and divided the lateral and posterior ligaments, the forearm is strongly flexed and the ends of the bone turned out and sawn off. The section of the humerus should be through

the base of the condyles, that of the ulna and radius should be just below the level of the lesser sigmoid cavity of the ulna and the neck of the radius. In this operation the object is to obtain such union as shall allow free motion of the bones of the forearm; and, therefore, passive motion must be commenced early, that is to say, about the tenth day.

VI. Radio-ulnar Articulations.

The articulation of the radius with the ulna is effected by ligaments which connect together both extremities as well as the shafts of these bones. They may, consequently, be subdivided into three sets: 1, the superior radio-ulnar, which is a portion of the elbow-joint; 2, the middle radio-ulnar; and, 3, the inferior radio-ulnar articulations.

1. SUPERIOR RADIO-ULNAR ARTICULATION.

This articulation is a trochoid or pivot-joint. The bones entering into its formation are the inner side of the circumference of the head of the radius rotating within the lesser sigmoid cavity of the ulna. Its only ligament is the *annular* or *orbicular*.

The **Orbicular Ligament** (Fig. 172) is a strong, flat band of ligamentous fibres, which surrounds the head of the radius, and retains it in firm connection with the lesser sigmoid cavity of the ulna. It forms about four-fifths of an osseo-fibrous ring, attached by each end to the extremities of the lesser sigmoid cavity, and is smaller at the lower part of its circumference than above, by which means the head of the radius is more securely held in its position. Its *outer surface*, is strengthened by the external lateral ligament of the elbow, and affords origin to part of the Supinator brevis muscle. Its *inner surface* is smooth, and lined by synovial membrane. The synovial membrane is continuous with that which lines the elbow-joint.

Actions.—The movement which takes place in this articulation is limited to rotation of the head of the radius within the orbicular ligament, and upon the lesser sigmoid cavity of the ulna, rotation forward being called *pronation*; rotation backward, *supination*. Supination is performed by the Biceps and Supinator brevis, assisted to a slight extent by the Extensor muscles of the thumb and, in certain positions, by the Supinator longus. Pronation is performed by the Pronator radii teres and the Pronator quadratus, assisted, in some positions, by the Supinator longus.

Surface Form.—The position of the superior radio-ulnar joint is marked on the surface of the body by the little dimple on the back of the elbow which indicates the position of the head of the radius.

Surgical Anatomy.—Dislocation of the head of the radius alone is not an uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the orbicular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children in lifting them from the ground by the hand or forearm. It is believed that the head of the radius is displaced downward in the orbicular ligament, the upper border of which becomes folded over the head of the radius, between it and the capitulum of the humerus.

2. MIDDLE RADIO-ULNAR UNION.

The interval between the shafts of the radius and ulna is occupied by two ligaments.

Oblique.

Interosseous.

The **Oblique** or **Round Ligament** (Fig. 171) is a small, flattened fibrous band which extends obliquely downward and outward from the tubercle of the ulna at the base of the coronoid process to the radius a little below the bicipital tuberosity. Its fibres run in the opposite direction to those of the interosseous ligament, and it appears to be placed as a substitute for it in the upper part of the interosseous interval. This ligament is sometimes wanting.

The **Interosseous Membrane** is a broad and thin plane of fibrous tissue descending obliquely downward and inward, from the interosseous ridge on the radius to that

FIG. 174.—Ligaments of wrist and hand. Anterior view.

on the ulna. It is deficient above, commencing about an inch beneath the tubercle of the radius; is broader in the middle than at either extremity; and presents an oval aperture just above its lower margin for the passage of the anterior interosseous vessels to the back of the forearm. This ligament serves to connect the bones and to increase the extent of surface for the attachment of the deep muscles. Between its upper border and the oblique ligament an interval exists through which the posterior interosseous vessels pass. Two or three fibrous bands are occasionally found on the posterior surface of this membrane which descend obliquely from the ulna toward the radius, and which have consequently a direction contrary to that of the other fibres. It is in relation, *in front*, by its upper three-fourths with the Flexor longus pollicis on the outer side, and with the Flexor profundus digitorum on the inner, lying upon the interval between which are the anterior interosseous vessels and nerve; by its lower fourth, with the Pronator quadratus; *behind*, with the Supinator brevis, Extensor ossis metacarpi pollicis, Extensor brevis pollicis, Extensor longus pollicis, Extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

3. INFERIOR RADIO-ULNAR ARTICULATION.

This is a pivot-joint, formed by the head of the ulna received into the sigmoid cavity at the inner side of the lower end of the radius. The articular surfaces are covered by a thin layer of cartilage, and connected together by the following ligaments:

Anterior Radio-ulnar.	Posterior Radio-ulnar.
Interarticular Fibro-cartilage.	

The **Anterior Radio-ulnar Ligament** (Fig. 174) is a narrow band of fibres extending from the anterior margin of the sigmoid cavity of the radius to the anterior surface of the head of the ulna.

The **Posterior Radio-ulnar Ligament** (Fig. 175) extends between similar points on the posterior surface of the articulation.

The **Interarticular Fibro-cartilage** (Fig. 177) is triangular in shape, and is

placed transversely beneath the head of the ulna, binding the lower end of this bone and the radius firmly together. Its periphery is thicker than its centre, which is thin and occasionally perforated. It is attached by its apex to a depression which separates the styloid process of the ulna from the head of that bone; and by its base, which is thin, to the prominent edge of the radius, which separates the sigmoid cavity from the carpal articulating surface. Its margins are united to the ligaments of the wrist-joint. Its *upper surface*, smooth and concave, articulates with the head of the ulna, forming an arthrodial joint; its *under surface*, also concave and smooth, forms part of the wrist-joint and articulates with the cuneiform and inner part of the semilunar bone. Both surfaces are lined by a synovial membrane—the upper surface, by one peculiar to the radio-ulnar articulation; the under surface, by the synovial membrane of the wrist.

FIG. 175.—Ligaments of wrist and hand. Posterior view.

The **Synovial Membrane** (Fig. 177) of this articulation has been called, from its extreme looseness, the *membrana sacciformis*; it extends horizontally inward between the head of the ulna and the interarticular fibro-cartilage, and upward between the radius and the ulna, forming here a very loose *cul-de-sac*. The quantity of synovia which it contains is usually considerable.

Actions.—The movement in the inferior radio-ulnar articulation is just the reverse of that in the superior radio-ulnar joint. It consists of a movement of rotation of the lower end of the radius round an axis which corresponds to the centre of the head of the ulna. When the radius rotates forward, *pronation* of the forearm and hand is the result; and when backward, *supination*. It will thus be seen that in pronation and supination of the forearm and hand the radius describes a segment of a cone, the axis of which extends from the centre of the head of the radius to the middle of the head of the ulna. In this movement, however, the ulna is not quite stationary, but rotates a little in the opposite direction. So that it also describes the segment of a cone, though of smaller size than that described by the radius. The movement which causes this alteration in the position of the head of the ulna takes place principally at the shoulder-joint by a rotation of the humerus, but possibly also to a slight extent at the elbow-joint.¹

Surface Form.—The position of the inferior radio-ulnar joint may be ascertained by feeling for a slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

¹ See *Journ. of Anat. and Phys.*, vol. xix., parts ii., iii., and iv.

The *Arteries* supplying the joint are the anterior and posterior carpal branches of the radial and ulnar, the anterior and posterior interosseous, and some ascending branches from the deep palmar arch.

The *Nerves* are derived from the ulnar and posterior interosseous.

Actions.—The movements permitted in this joint are flexion, extension, abduction, adduction, and circumduction. Its actions will be further studied with those of the carpus, with which they are combined.

Surface Form.—The line of the radio-carpal joint is on a level with the apex of the styloid process of the ulna.

Surgical Anatomy.—The wrist-joint is rarely dislocated, its strength depending mainly upon the numerous strong tendons which surround the articulation. Its security is further provided for by the number of small bones of which the carpus is made up, and which are united by very strong ligaments. The slight movement which takes place between the several bones serves to break the jars that result from falls or blows on the hand. Dislocation backward, which is the more common, simulates to a considerable extent Colles' fracture of the radius, and is liable to be mistaken for it. The diagnosis can be easily made out by observing the relative position of the styloid processes of the radius and the ulna. In the natural condition the styloid process of the radius is on a lower level—*i. e.* nearer the ground—when the arm hangs by the side, than that of the ulna, and the same would be the case in dislocation. In Colles' fracture, on the other hand, the styloid process of the radius is on the same, or even a higher level than that of the ulna.

The wrist-joint is occasionally the seat of acute synovitis, the result of traumatism or arising in the rheumatic or pyæmic state. When the synovial sac is distended with fluid, the swelling is greatest on the dorsal aspect of the wrist, showing a general fulness, with some bulging between the tendons. The inflammation is prone to extend to the intercarpal joints and to attack also the sheaths of the tendons in the neighborhood. Chronic inflammation of the wrist is generally tubercular, and often leads to similar disease in the synovial sheaths of adjacent tendons and of the intercarpal joints. The disease, therefore, when progressive, often leads to necrosis of the carpal bones, and the result is often unsatisfactory.

VIII. Articulations of the Carpus.

These articulations may be subdivided into three sets:

1. The Articulations of the First Row of Carpal Bones.
2. The Articulations of the Second Row of Carpal Bones.
3. The Articulations of the Two Rows with each other.

1. ARTICULATIONS OF THE FIRST ROW OF CARPAL BONES.

These are arthrodial joints. The ligaments connecting the scaphoid, semilunar, and cuneiform bones are—

Dorsal.

Palmar.

Two Interosseous.

The **Dorsal Ligaments** are placed transversely behind the bones of the first row; they connect the scaphoid and semilunar and the semilunar and cuneiform.

The **Palmar Ligaments** connect the scaphoid and semilunar and the semilunar and cuneiform bones; they are less strong than the dorsal, and placed very deeply below the anterior ligament of the wrist.

The **Interosseous Ligaments** (Fig. 177) are two narrow bundles of fibrous tissue connecting the semilunar bone on one side with the scaphoid, and on the other with the cuneiform. They are on a level with the superior surfaces of these bones, and close the upper part of the spaces between them. Their upper surfaces are smooth, and form with the bones the convex articular surfaces of the wrist-joint.

The ligaments connecting the pisiform bone are—

Capsular.

Two Palmar ligaments.

The **Capsular Ligament** is a thin membrane which connects the pisiform bone to the cuneiform. It is lined with a separate synovial membrane.

The **two Palmar Ligaments** are two strong fibrous bands which connect the

pisiform to the unciform, the *piso-uncinate*, and to the base of the fifth metacarpal bone, the *piso-metacarpal ligament* (Fig. 174).

2. ARTICULATIONS OF THE SECOND ROW OF CARPAL BONES.

These are also arthrodial joints. The articular surfaces are covered with cartilage, and connected by the following ligaments:

Dorsal.

Palmar.

Three Interosseous.

The **Dorsal Ligaments** extend transversely from one bone to another on the dorsal surface, connecting the trapezium with the trapezoid, the trapezoid with the os magnum, and the os magnum with the unciform.

The **Palmar Ligaments** have a similar arrangement on the palmar surface.

The **three Interosseous Ligaments**, much thicker than those of the first row, are placed one between the os magnum and the unciform, a second between the os magnum and the trapezoid, and a third between the trapezium and trapezoid. The first of these is much the strongest, and the third is sometimes wanting.

3. ARTICULATIONS OF THE TWO ROWS OF CARPAL BONES WITH EACH OTHER.

The joint between the scaphoid, semilunar, and cuneiform, and the second row of the carpus, or the *mid-carpal joint*, is made up of three distinct portions; in the centre the head of the os magnum and the superior surface of the unciform articulate with the deep, cup-shaped cavity formed by the scaphoid and semilunar bones, and constitute a sort of ball-and-socket joint. On the outer side the trapezium and trapezoid articulate with the scaphoid, and on the inner side the unciform articulates with the cuneiform, forming gliding joints.

The ligaments are—

Anterior or Palmar.

External Lateral.

Posterior or Dorsal.

Internal Lateral.

The **Anterior or Palmar Ligaments** consist of short fibres, which pass, for the most part, from the palmar surface of the bones of the first row to the front of the os magnum.

The **Posterior or Dorsal Ligaments** consist of short, irregular bundles of fibres passing between the bones of the first and second row on the dorsal surface of the carpus.

The **Lateral Ligaments** are very short: they are placed, one on the radial, the other on the ulnar side of the carpus; the former, the stronger and more distinct, connecting the scaphoid and trapezium bones, the latter the cuneiform and unciform; they are continuous with the lateral ligaments of the wrist-joint. In addition to these ligaments, a slender interosseous band sometimes connects the os magnum and the scaphoid.

The **Synovial Membrane of the Carpus** is very extensive: it passes from the under surface of the scaphoid, semilunar, and cuneiform bones to the upper surface of the bones of the second row, sending upward two prolongations—between the scaphoid and semilunar and the semilunar and cuneiform; sending downward three prolongations between the four bones of the second row, which are further continued onward into the carpo-metacarpal joints of the four inner metacarpal bones, and also for a short distance between the metacarpal bones. There is a separate synovial membrane between the pisiform and cuneiform bones.

Actions.—The articulation of the hand and wrist, considered as a whole, is divided into three parts: (1) the radius and the interarticular fibro-cartilage; (2) the meniscus, formed by the scaphoid, semilunar, and cuneiform, the pisiform bone having no essential part in the movements of the hand; (3) the hand proper, the metacarpal bones with the four carpal bones on which they are supported—viz. the trapezium, trapezoid, os magnum, and unciform. These three elements form

two joints: (1) the superior (wrist-joint proper), between the meniscus and bones of the forearm; (2) the inferior, between the hand and meniscus (transverse or mid-carpal joint).

(1) The articulation between the forearm and carpus is a true condyloid articulation, and therefore all movements but rotation are permitted. Flexion and extension are the most free, and of these a greater amount of extension than flexion is permitted on account of the articulating surfaces extending farther on the dorsal than on the palmar aspect of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. A certain amount of adduction (or ulnar flexion) and abduction (or radial flexion) is also permitted. Of these the former is considerably greater in extent than the latter. In this movement the carpus revolves upon an antero-posterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the consecutive movements of adduction, extension, abduction, and flexion, with intermediate movements between them. There is no rotation, but this is provided for by the supination and pronation of the radius on the ulna. The movement of *flexion* is performed by the Flexor carpi radialis, the Flexor carpi ulnaris, and the Palmaris longus; *extension*, by the Extensor carpi radialis longior et brevior and the Extensor carpi ulnaris; *adduction* (ulnar flexion), by the Flexor carpi ulnaris and the Extensor carpi ulnaris; and *abduction* (radial flexion), by the Extensors of the thumb and the Extensor carpi radialis longior et brevior and the Flexor carpi radialis.

(2) The chief movements permitted in the transverse or mid-carpal joint are flexion and extension and a slight amount of rotation. In flexion and extension, which is the movement most freely enjoyed, the trapezium and trapezoid on the radial side and the unciform on the ulnar side glide forward and backward on the scaphoid and cuneiform respectively, while the head of the os magnum and the superior surface of the unciform rotate in the cup-shaped cavity of the scaphoid and semilunar. Flexion at this joint is freer than extension. A very trifling amount of rotation is also permitted, the head of the os magnum rotating round a vertical axis drawn through its own centre, while at the same time a slight gliding movement takes place in the lateral portions of the joint.

IX. Carpo-metacarpal Articulations.

1. ARTICULATION OF THE METACARPAL BONE OF THE THUMB WITH THE TRAPEZIUM.

This is a joint of reciprocal reception, and enjoys great freedom of movement, on account of the configuration of its articular surfaces, which are saddle-shaped, so that, on section, each bone appears to be received into a cavity in the other, according to the direction in which they are cut. The joint is surrounded by a capsular ligament.

The **Capsular Ligament** is thick, but loose, and passes from the circumference of the upper extremity of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest externally and behind, and lined by a separate *synovial membrane*.

Movements.—In the articulation of the metacarpal bone of the thumb with the trapezium the movements permitted are flexion, extension, adduction, abduction, and circumduction. When the joint is flexed the metacarpal bone is brought in front of the palm and the thumb is gradually turned to the fingers. It is by this peculiar movement that the tip of the thumb is opposed to the other digits; for by slightly flexing the fingers the palmar surface of the thumb can be brought in contact with their palmar surfaces one after another.

2. ARTICULATIONS OF THE METACARPAL BONES OF THE FOUR INNER FINGERS WITH THE CARPUS.

The joints formed between the carpus and four inner metacarpal bones are arthrodial joints. The ligaments are—

Dorsal.

Palmar.

Interosseous.

The **Dorsal Ligaments**, the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surface. The second metacarpal bone receives two fasciculi—one from the trapezium, the other from the trapezoid; the third metacarpal receives two—one from the trapezoid and one from the os magnum; the fourth two—one from the os magnum and one from the unciform; the fifth receives a single fasciculus from the unciform bone, which is continuous with a similar ligament on the palmar surface, forming an incomplete capsule.

The **Palmar Ligaments** have a somewhat similar arrangement on the palmar surface, with the exception of the third metacarpal, which has three ligaments—an external one from the trapezium, situated above the sheath of the tendon of the *Flexor carpi radialis*; a middle one, from the os magnum; and an internal one, from the unciform.

The **Interosseous Ligaments** consist of short, thick fibres, which are limited to one part of the carpo-metacarpal articulation; they connect the contiguous inferior angles of the os magnum and unciform with the adjacent surfaces of the third and fourth metacarpal bones.

The **Synovial Membrane** is a continuation of that between the two

FIG. 177.—Vertical section through the articulations at the wrist, showing the five synovial membranes.

rows of carpal bones. Occasionally, the articulation of the unciform with the fourth and fifth metacarpal bones has a separate synovial membrane.

The synovial membranes of the wrist and carpus (Fig. 177) are thus seen to be five in number. The *first*, the *membrana sacciformis*, passes from the lower end of the ulna to the sigmoid cavity of the radius, and lines the upper surface of the interarticular fibro-cartilage. The *second* passes from the lower end of the radius and interarticular fibro-cartilage above to the bones of the first row below. The *third*, the most extensive, passes between the contiguous margins of the two rows of carpal bones—between the bones of the second row to the carpal extremities of the four inner metacarpal bones. The *fourth*, from the margin of the trapezium to the metacarpal bone of the thumb. The *fifth*, between the adjacent margins of the cuneiform and pisiform bones.

Actions.—The movement permitted in the carpo-metacarpal articulations of the four inner fingers is limited to a slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. Thus the articulation of the metacarpal bone of the little finger is most movable, then that of the ring finger. The metacarpal bones of the index and middle fingers are almost immovable.

3. ARTICULATIONS OF THE METACARPAL BONES WITH EACH OTHER.

The carpal extremities of the four inner metacarpal bones articulate with one another at each side by small surfaces covered with cartilages, and connected together by dorsal, palmar, and interosseous ligaments.

The **Dorsal** and **Palmar Ligaments** pass transversely from one bone to another on the dorsal and palmar surfaces. The *Interosseous Ligaments* pass between their contiguous surfaces, just beneath their lateral articular facets.

The **Synovial Membrane** between the lateral facets is a reflection from that between the two rows of carpal bones.

The **Transverse Metacarpal Ligaments** (Fig. 178) is a narrow fibrous band which passes transversely across the anterior surfaces of the digital extremities of the four inner metacarpal bones, connecting them together. It is blended anteriorly with the anterior (glenoid) ligament of the metacarpal-phalangeal articulations. To its posterior border is connected the fascia which covers the Interossei muscles. Its anterior surface is concave where the flexor tendons pass over it. Behind it the tendons of the Interossei muscles pass to their insertion.

X. Metacarpo-phalangeal Articulations (Fig. 178).

These articulations are of the condyloid kind, formed by the reception of the rounded head of the metacarpal bone into a shallow cavity in the extremity of the first phalanx. The ligaments are—

Anterior.

Two Lateral.

The **Anterior Ligaments** (*Glenoid Ligaments* of Cruveilhier) are thick, dense, fibrous structures, placed on the palmar surface of the joints in the intervals between the lateral ligaments, to which they are connected; they are loosely united to the metacarpal bone, but very firmly to the base of the first phalanges. Their palmar surface is intimately blended with the transverse metacarpal ligament, and presents a groove for the passage of the flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep surface they form part of the articular surface for the head of the metacarpal bone, and are lined by a synovial membrane.

The **Lateral Ligaments** are strong, rounded cords placed one on each side of the joint, each being attached by one extremity to the posterior tubercle on the side of the head of the metacarpal bone, and by the other to the contiguous extremity of the phalanx.

Actions.—The movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction; the lateral movements are very limited.

FIG. 178.—Articulations of the phalanges.

Surface Form.—The prominences of the knuckles do not correspond to the position of the joints either of the metacarpo-phalangeal or interphalangeal articulations. These prominences are invariably formed by the distal ends of the proximal bone of each joint, and the line indicating the position of the joint must be sought considerably in front of the middle of the knuckle. The usual rule for finding these joints is to flex the distal phalanx on the proximal one to a right angle; the position of the joint is then indicated by an imaginary line drawn along the middle of the lateral aspect of the proximal phalanx.

XI. Articulations of the Phalanges.

These are ginglymus joints. The ligaments are—

Anterior.

Two Lateral.

The arrangement of these ligaments is similar to those in the metacarpo-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the anterior and lateral ligaments.

ARTICULATIONS OF THE LOWER EXTREMITY.

The articulations of the Lower Extremity comprise the following groups: I. The hip-joint. II. The knee-joint. III. The articulations between the tibia and fibula. IV. The ankle-joint. V. The articulations of the tarsus. VI. The tarso-metatarsal articulations. VII. Articulations of the metatarsal bones with each other. VIII. The metatarso-phalangeal articulations. IX. The articulations of the phalanges.

I. Hip-joint (Fig. 179).

This articulation is an enarthrodial or ball-and-socket joint, formed by the reception of the head of the femur into the cup-shaped cavity of the acetabulum. The articulating surfaces are covered with cartilage, that on the head of the femur being thicker at the centre than at the circumference, and covering the entire surface, with the exception of a depression just below its centre for the ligamentum teres; that covering the acetabulum is much thinner at the centre than at the circumference. It forms an incomplete cartilaginous ring of a horseshoe shape, being deficient below, where there is a circular depression, which is occupied in the recent state by a mass of fat covered by synovial membrane. The ligaments of the joints are the

Capsular.

Teres.

Ilio-femoral.

Cotyloid.

Transverse.

The **Capsular Ligament** is a strong, dense, ligamentous capsule, embracing the margin of the acetabulum above and surrounding the neck of the femur below. Its *upper circumference* is attached to the acetabulum, above and behind, two or three lines external to the cotyloid ligament; but in front it is attached to the outer margin of this ligament, and opposite to the notch where the margin of this cavity is deficient, it is connected to the transverse ligament, and by a few fibres to the edge of the obturator foramen. Its *lower circumference* surrounds the neck of the femur, being attached, in front, to the spiral or anterior intertrochanteric line; above, to the base of the neck; behind, to the neck of the bone, about half an inch above the posterior intertrochanteric line. From this insertion the fibres are reflected upward over the neck of the femur, forming a sort of tubular sheath (the *cervical reflection*), which blends with the periosteum and can be traced as far as the articular cartilage. On the surface of the neck of the femur some of these reflected fibres are raised into longitudinal folds, termed *retinacula*. It is much thicker at the upper and fore part of the joint, where the greatest amount of

resistance is required, than below and internally, where it is thin, loose, and longer than in any other part. It consists of two sets of fibres, circular and longitudinal. The circular fibres (*zona orbicularis*) are most abundant at the lower and back part of the capsule, and form a sling or collar around the neck of the femur. Anteriorly they blend with the deep surface of the ilio-femoral ligament, and through its medium reach the anterior inferior spine of the ilium. The longitudinal fibres are greatest in amount at the upper and front part of the cap-

FIG. 179.—Left hip-joint laid open.

sule, where they form distinct bands or accessory ligaments, of which the most important is the *ilio-femoral*. The other accessory bands are known as the *pubo-femoral*, passing from the ilio-pectineal eminence to the front of the capsule; and *ischio-capsular*, passing from the ischium, just below the acetabulum, to blend with the circular fibres at the lower part of the joint. The external surface (Fig. 164, page 241) is rough, covered by numerous muscles, and separated in front from the Psoas and Iliacus by a synovial bursa, which not infrequently communicates, by a circular aperture, with the cavity of the joint. It differs from the capsular ligament of the shoulder in being much less loose and lax, and in not being perforated for the passage of a tendon.

The **Ilio-femoral Ligament** (Figs. 164 and 180) is an accessory band of fibres extending obliquely across the front of the joint; it is intimately connected with the capsular ligament, and serves to strengthen it in this situation. It is attached, above, to the lower part of the anterior inferior spine of the ilium; and, diverging below, forms two bands, of which one passes downward to be inserted into the lower part of the anterior intertrochanteric line; the other passes downward and outward to be inserted into the upper part of the same line and adjacent part of the neck of the femur. Between the two bands is a thinner part of the capsule. Sometimes there is no division, but the ligament spreads out into a flat, triangular band, which is attached below into the whole length of the anterior intertrochanteric line. This ligament is frequently called the Y-shaped ligament of Bigelow;

and the outer or upper of the two bands is sometimes described as a separate ligament, under the name of the *ilio-trochanteric ligament*.

The **Ligamentum Teres** is a triangular band implanted by its apex into the depression a little behind and below the centre of the head of the femur, and by its broad base into the margins of the cotyloid notch, becoming blended with the transverse ligament. It is formed of connective tissue, surrounded by a tubular sheath of synovial membrane. Sometimes only the synovial fold exists, or the ligament may be altogether absent. The ligament is made tense when the hip is semiflexed, and the limb then adducted and rotated outward; it is, on the other hand, relaxed when the limb is abducted. It has, however, but little influence as a ligament, though it may to a certain extent limit movement, and would appear to be merely a modi-

FIG. 180.—Hip-joint, showing the ilio-femoral ligament. (After Bigelow.)

FIG. 181.—Vertical section through hip-joint. (Henle.)

fication of the folds which in other joints fringe the margins of reflection of synovial membranes (see page 218).

The **Cotyloid Ligament** is a fibro-cartilaginous rim attached to the margin of the acetabulum, the cavity of which deepens; at the same time it protects the edges of the bone and fills up the inequalities on its surface. It bridges over the notch as the *transverse ligament*, and thus forms a complete circle, which closely surrounds the head of the femur, and assists in holding it in its place, acting as a sort of valve. It is prismoid on section, its base being attached to the margin of the acetabulum, and its opposite edge being free and sharp; whilst its two surfaces are invested by synovial membrane, the external one being in contact with the capsular ligament, the internal one being inclined inward, so as to narrow the acetabulum and embrace the cartilaginous surface of the head of the femur. It is much thicker above and behind than below and in front, and consists of close, compact fibres, which arise from different points of the circumference of the acetabulum and interlace with each other at very acute angles.

The **Transverse Ligament** is in reality a portion of the cotyloid ligament, though differing from it in having no cartilage-cells amongst its fibres. It consists of strong, flattened fibres, which cross the notch at the lower part of the acetabulum and convert it into a foramen. Thus an interval is left beneath the ligament for the passage of nutrient vessels to the joint.

The **Synovial Membrane** is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers all that portion of the neck which is contained within the joint; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the cotyloid ligament and the mass of fat contained in the depression at the bottom of the acetabulum.

FIG. 182.—Relation of muscles to hip-joint. (Henle.)

ulum, and is prolonged in the form of a tubular sheath around the ligamentum teres, as far as the head of the femur. It sometimes communicates through a hole in the capsular ligament between the inner band of the Y-shaped ligament and the pubo-femoral ligament with a bursa situated on the under surface of the Ilio-psoas muscle.

The muscles in relation with the joint are, in front, the Psoas and Iliacus, separated from the capsular ligament by a synovial bursa; above, the reflected head of the Rectus and Gluteus minimus, the latter being closely adherent to the capsule; internally, the Obturator externus and Pectineus; behind, the Piriformis, Gemellus superior, Obturator internus, Gemellus inferior, Obturator externus, and Quadratus femoris (Fig. 182).

The arteries supplying the joint are derived from the obturator, sciatic, internal circumflex, and gluteal.

The nerves are articular branches from the sacral plexus, great sciatic, obturator, accessory obturator, and a filament from the branch of the anterior crural supplying the Rectus.

Actions.—The movements of the hip are very extensive, and consist of flexion, extension, adduction, abduction, circumduction, and rotation.

The hip-joint presents a very striking contrast to the shoulder-joint in the much more complete mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as we have seen, the head of the humerus is not adapted at all in size to the glenoid cavity, and is hardly restrained in any of its ordinary movements by the capsular ligament. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum

for a distance extending over nearly half a sphere, and at the margin of the bony cup it is still more closely embraced by the cotyloid ligament, so that the head of the femur is held in its place by that ligament even when the fibres of the capsule have been quite divided (Humphry). The anterior portion of the capsule, described as the ilio-femoral ligament, is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk. That is to say, this ligament is the chief agent in maintaining the erect position without muscular fatigue; for a vertical line passing through the centre of gravity of the trunk falls behind the centres of rotation in the hip-joints, and therefore the pelvis tends to fall backward, but is prevented by the tension of the ilio-femoral and capsular ligaments. The security of the joint may be also provided for by the two bones being directly united through the ligamentum teres; but it is doubtful whether this so-called ligament can have much influence upon the mechanism of the joint. Flexion of the hip-joint is arrested by the soft parts of the thigh and abdomen being brought into contact when the leg is flexed on the thigh; and by the action of the hamstring muscles when the leg is extended;¹ extension, by the tension of the ilio-femoral ligament and front of the capsule; adduction, by the thighs coming into contact; adduction, with flexion by the outer band of the ilio-femoral ligament, the outer part of the capsular ligament; abduction, by the inner band of the ilio-femoral ligament and the pubo-femoral band; rotation outward, by the outer band of the ilio-femoral ligament; and rotation inward, by the ischio-capsular ligament and the hinder part of the capsule. The muscles which *flex* the femur on the pelvis are the Psoas, Iliacus, Rectus, Sartorius, Pectineus, Adductor longus and brevis, and the anterior fibres of the Gluteus medius and minimus. *Extension* is mainly performed by the Gluteus maximus, assisted by the hamstring muscles. The thigh is *adducted* by the Adductor magnus, longus, and brevis, the Pectineus, the Gracilis, and lower part of the Gluteus maximus, and *abducted* by the Gluteus medius and minimus and upper part of the Gluteus maximus. The muscles which *rotate* the thigh *inward* are the anterior fibres of the Gluteus medius, the Gluteus minimus, and the Tensor fasciæ femoris; while those which rotate it *outward* are the posterior fibres of the Gluteus medius, the Piriformis, Obturator externus and internus, Gemellus superior and inferior, Quadratus femoris, Iliacus, Gluteus maximus, the three Adductors, the Pectineus, and the Sartorius.

Surface Form.—A line drawn from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium (Nélaton's line) runs through the centre of the acetabulum, and would, therefore, indicate the level of the hip-joint; or, in other words, the upper border of the great trochanter, which lies on Nélaton's line, is on a level with the centre of the hip-joint.

Surgical Anatomy.—In dislocation of the hip "the head of the thigh-bone may rest at any point around its socket" (Bryant); but whatever position the head ultimately assumes, the primary displacement is generally downward and inward, the capsule giving way at its weakest—that is, its lower and inner—part. The situation that the head of the bone subsequently assumes is determined by the degree of flexion or extension, and of outward or inward rotation of the thigh at the moment of luxation, influenced, no doubt, by the ilio-femoral ligament, which is not easily ruptured. When, for instance, the head is forced backward, this ligament forms a fixed axis, round which the head of the bone rotates, and is thus driven on to the dorsum of the ilium. The ilio-femoral ligament also influences the position of the thigh in the various dislocations: in the dislocations backward it is tense, and produces inversion of the limb; in the dislocation on to the pubes it is relaxed, and therefore allows the external rotators to evert the thigh; while in the thyroid dislocation it is tense and produces flexion. The muscles inserted into the upper part of the femur, with the exception of the Obturator internus, have very little direct influence in determining the position of the bone. But Bigelow has endeavored to show that the Obturator internus is the principal agent in determining whether, in the backward dislocations, the head of the bone shall be ultimately lodged on the dorsum of the ilium or in or near the sciatic notch. In both dislocations the head passes, in the first instance, in the same direction; but, as Bigelow asserts, in the displacement on to the dorsum, the head of the bone travels up behind the acetabulum, in front of the muscle; while in the dislocation into the

¹ The hip-joint cannot be completely flexed, in most persons, without at the same time flexing the knee, on account of the shortness of the hamstring muscles.—Cleland, *Journ. of Anat. and Phys.*, No. 1, Old Series, p. 87.

sciatic notch, the head passes behind the muscle, and is therefore prevented from reaching the dorsum, in consequence of the tendon of the muscle arching over the neck of the bone, and so remains in the neighborhood of the sciatic notch. Bigelow, therefore, distinguishes these two forms of dislocation by describing them as dislocations backward, "above and below," the Obturator internus.

The ilio-femoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as a fulcrum to a lever, of which the long arm is the shaft of the femur, and the short arm the neck of the bone.

The hip-joint is rarely the seat of acute synovitis from injury, on account of its deep position and its thick covering of soft parts. Acute inflammation may, and does, frequently occur as the result of constitutional conditions, as rheumatism, pyæmia, etc. When, in these cases, effusion takes place, and the joint becomes distended with fluid, the swelling is not very easy to detect on account of the thickness of the capsule and the depth of the articulation. It is principally to be found on the front of the joint, just internal to the ilio-femoral ligament; or behind, at the lower and back part. In these two places the capsule is thinner than elsewhere. Disease of the hip-joint is much more frequently of a chronic character and is usually of a tubercular origin. It begins either in the bones or in the synovial membrane, more frequently in the former, and probably, in most cases, at the growing, highly vascular tissue in the neighborhood of the epiphysal cartilage. In this respect it differs very materially from tubercular arthritis of the knee, where the disease usually commences in the synovial membrane. The reasons why the disease so frequently begins in this situation are twofold: first, this part being the centre of rapid growth, its nutrition is unstable and apt to pass into inflammatory action; and, secondly, great strain is thrown upon it, from the frequency of falls and blows upon the hip, which causes crushing of the epiphysal cartilage or the cancellous tissue in its neighborhood, with the results likely to follow such an injury. In addition to these, the depth of the joint protects it from the causes of synovitis.

In chronic hip-disease the affected limb assumes an altered position, the cause of which it is important to understand. In the early stage of a typical case the limb is flexed, abducted, and rotated outward. In this position all the ligaments of the joint are relaxed: the front of the capsule by flexion; the outer band of the ilio-femoral ligament by abduction; and the inner band of this ligament and the back of the capsule by rotation outward. It is, therefore, the position of the greatest ease. The condition is not quite obvious at first upon examining a patient. If the patient is laid in the supine position, the affected limb will be found to be extended and parallel with the other. But it will be found that the pelvis is tilted downward on the diseased side and the limb apparently longer than its fellow, and that the lumbar spine is arched forward (lordosis). If now the thigh is abducted and flexed, the tilting downward and the arching forward of the pelvis disappears. The condition is thus explained. A limb which is flexed and abducted is obviously useless for progression, and, in order to overcome the difficulty, the patient depresses the affected side of his pelvis in order to produce parallelism of his limbs, and at the same time rotates his pelvis on its transverse horizontal axis, so as to direct the limb downward instead of forward. In the latter stages of the disease the limb becomes flexed and abducted and inverted. This position probably depends upon muscular action, at all events as regards the adduction. The Adductor muscles are supplied by the obturator nerve, which also largely supplies the joint. These muscles are therefore thrown into reflex action by the irritation of the peripheral terminations of this nerve in the inflamed articulation. Osteo-arthritis is not uncommon in the hip-joint, and it is said to be more common in the male than in the female, in whom the knee-joint is more frequently affected. It is a disease of middle age or more advanced period of life.

Congenital dislocation is more commonly met with in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii. It gives rise to extreme lordosis, and a waddling gait is noticed as soon as the child commences to walk.

Excision of the hip may be required for disease or for injury, especially gunshot. It may be performed either by an anterior incision or a posterior one. The former one entails less interference with important structures, especially muscles, than the posterior one, but permits of less efficient drainage. In these days, however, when the surgeon aims at securing healing of his wound without suppuration, this second desideratum is not of so much importance. In the operation in front the surgeon makes an incision three to four inches in length, starting immediately below and external to the anterior superior spinous process of the ilium, downward and inward between the Sartorius and Tensor fasciæ femoris, to the neck of the bone, dividing the capsule at its upper part. A narrow-bladed saw now divides the neck of the femur, and the head of the bone is extracted with sequestrum forceps. All diseased tissue is carefully removed with a sharp spoon or seissors, and the cavity thoroughly flushed out with a hot antiseptic fluid.

The posterior method consists in making an incision three or four inches long, commencing midway between the top of the great trochanter and the anterior superior spine, and ending over the shaft, just below the trochanter. The muscles are detached from the great trochanter, and the capsule opened freely. The head and neck are freed from the soft parts and the bone sawn through just below the top of the trochanter with a narrow saw. The head of the bone is then levered out of the acetabulum. In both operations, if the acetabulum is eroded, it must be freely gouged.

II. Knee-joint.

The knee-joint was formerly described as a ginglymus or hinge-joint, but is really of a much more complicated character. It must be regarded as consisting of three articulations in one: one between each condyle of the femur and the corresponding tuberosity of the tibia, which are condyloid joints, and one between the patella and the femur, which is partly arthrodial, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from the study of the articulation in some of the lower mammals, where three synovial membranes are sometimes found, corresponding to these three subdivisions, either entirely distinct or only connected together by small communications. This view is further rendered probable by the existence of the two crucial ligaments within the joint, which must be regarded as the external and internal lateral ligaments of the inner and outer joints respectively. The existence of the *ligamentum mucosum* would further indicate a tendency to separation of the synovial cavity into two minor sacs, one corresponding to each joint.

The bones entering into the formation of the knee-joint are the condyles of the femur above, the head of the tibia below, and the patella in front. The bones are connected together by ligaments, some of which are placed on the exterior of the joint, while others occupy its interior.

 Ligamenta alaria. } ovia Membrane.

The **Anterior Ligament**, or **Ligamentum Patellæ** (Fig. 183), is the central portion of the common tendon of the Extensor muscles of the thigh which is continued from the patella to the tubercle of the tibia, supplying the place of an anterior ligament. It is a strong, flat, ligamentous band about three inches in length, attached, above, to the apex of the patella and the rough depression on its posterior surface; below, to the lower part of the tubercle of the tibia, its superficial fibres being continuous over the front of the patella with those of the tendon of the Quadriceps extensor. The lateral portions of the tendon of the Extensor muscles pass down on either side of the patella, attached to the borders of this bone and its ligament, to be inserted into the upper extremity of the tibia on each side of the tubercle; externally, these portions merge into the capsular ligament. They are termed *lateral patellar ligaments*. The posterior surface of the ligamentum patellæ can usually be easily separated from the front of the capsular ligament.

The **Posterior Ligament** (**Ligamentum Posticum Winslowii**) (Fig. 184) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached, above, to the upper margin of the intercondyloid notch of the femur, and below, to the posterior margin of the head of the tibia. Superficial to the main part of the ligament is a strong fasciculus derived from the tendon of the Semimembranosus, and passing from the back part of the inner tuberosity of the tibia obliquely upward and outward to the back part of the outer condyle of the femur. The posterior ligament forms part of the floor of the popliteal space, and the popliteal artery rests upon it.

The **Internal Lateral Ligament** is a broad, flat, membranous band, thicker behind than in front, and situated nearer to the back than the front of the joint. It is attached, above, to the inner tuberosity of the femur; below, to the inner tuberosity and inner surface of the shaft of the tibia to the extent of about two inches. It is crossed, at its lower part, by the tendons of the Sartorius, Gracilis,

and Semitendinosus muscles, a synovial bursa being interposed. Its *deep surface* covers the anterior portion of the tendon of the Semimembranosus, with which it is connected by a few fibres, the synovial membrane of the joint, and the inferior internal articular vessels and nerve; it is intimately adherent to the internal semilunar fibro-cartilage.

FIG. 183.—Right knee-joint. Anterior view.

FIG. 184.—Right knee-joint. Posterior view.

The **Long External Lateral Ligament** is a strong, rounded, fibrous cord situated nearer to the back than the front of the joint. It is attached, above, to the back part of the outer tuberosity of the femur; below, to the outer part of the head of the fibula. Its *outer surface* is covered by the tendon of the Biceps, which divides at its insertion into two parts, separated by the ligament. The ligament has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The **Short External Lateral Ligament** is an accessory bundle of fibres placed behind and parallel with the preceding, attached, above, to the lower and back part of the outer tuberosity of the femur; below, to the summit of the styloid process of the fibula. This ligament is intimately connected with the capsular ligament, and has, passing beneath it, the tendon of the Popliteus muscle and the inferior external articular vessels and nerve.

The **Capsular Ligament** consists of an exceedingly thin but strong, fibrous membrane which fills in the intervals left between the stronger bands above described, and is inseparably connected with them. In front it blends with and forms part of the lateral patellar ligaments and fills in the interval between the anterior and lateral ligaments of the joint, with which latter structures it is closely connected. Behind, it is formed chiefly of vertical fibres, which arise above from the condyles and intercondyloid notch of the femur, and is connected below with the back part of the head of the tibia, being closely united with the origins of

the Gastrocnemius, Plantaris, and Popliteus muscles. It passes in front of, but is inseparably connected with, the posterior ligament.

The **Crucial** are two interosseous ligaments of considerable strength situated in the interior of the joint, nearer its posterior than its anterior part. They are called *crucial* because they cross each other somewhat like the lines of the letter X; and have received the names *anterior* and *posterior*, from the position of their attachment to the tibia.

FIG. 185.—Right knee-joint. Showing internal ligaments.

The **Anterior**, or **External Crucial Ligament** (Fig. 185), is attached to the depression in front of the spine of the tibia, being blended with the anterior extremity of the external semilunar fibro-cartilage, and, passing obliquely upward, backward, and outward, is inserted into the inner and back part of the outer condyle of the femur.

The **Posterior**, or **Internal Crucial Ligament**, is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the back part of the depression behind the spine of the tibia, to the popliteal notch, and to the posterior extremity of the external semilunar fibro-cartilage; and passes upward, forward, and inward, to be inserted into the outer and fore part of the inner condyle of the femur. It is in relation, in front, with the anterior crucial ligament; behind, with the capsular ligament.

The **Semilunar Fibro-cartilages** (Fig. 186) are two crescentic lamellæ which serve to deepen the surface of the head of the tibia, for articulation with the condyles of the femur. The circumference of each cartilage is thick, convex, and attached to the inside of the capsule of the knee; the inner border is thin, concave and free. Their upper surfaces are concave, and in relation with the condyles of the femur; their lower surfaces are flat, and rest upon the head of the tibia. Each cartilage covers nearly the outer two-thirds of the corresponding articular surface of the tibia, leaving the inner third uncovered; both surfaces are smooth and invested by synovial membrane.

FIG. 186.—Head of tibia, with semilunar cartilages, etc. Seen from above. Right side.

The **Internal Semilunar Fibro-cartilage** is nearly semicircular in form, a little elongated from before backward, and broader behind than in front; its anterior extremity, thin and pointed, is attached to a depression on the anterior margin of the head of the tibia, in front of the anterior crucial ligament; its posterior extremity is attached to the depression behind the spine, between the attachments of the external semilunar fibro-cartilage and the posterior crucial ligaments.

The **External Semilunar Fibro-cartilage** forms nearly an entire circle, covering a larger portion of the articular surface than the internal one. It is grooved on its outer side for the tendon of the Popliteus muscle. Its extremities, at their insertion, are interposed between the two extremities of the internal semilunar fibro-cartilage; the anterior extremity being attached in front of the spine of the tibia to the outer side of, and behind, the anterior crucial ligament, with which it blends; the posterior extremity being attached behind the spine of the tibia, in front of the posterior extremity of the internal semilunar fibro-cartilage. Just before its insertion posteriorly it gives off a strong fasciculus, the *ligament of Wrisberg*, which passes obliquely upward and outward, to be inserted into the inner condyle of the femur, close to the attachment of the posterior crucial ligament. Occasionally a small fasciculus is given off which passes forward to be inserted into the back part of the anterior crucial ligament. The external semilunar fibro-cartilage gives off from its anterior convex margin a fasciculus which forms the transverse ligament.

The **Transverse Ligament** is a band of fibres which passes transversely from the anterior convex margin of the external semilunar fibro-cartilage to the anterior convex margin of the internal semilunar fibro-cartilage; its thickness varies considerably in different subjects, and it is sometimes absent altogether.

The **Coronary Ligaments** are merely portions of the capsular ligament, which connect the circumference of each of the semilunar fibro-cartilages with the margin of the head of the tibia.

The **Synovial Membrane** of the knee-joint is the largest and most extensive in the body. Commencing at the upper border of the patella, it forms a short *cul-de-sac* beneath the Quadriceps extensor tendon of the thigh, on the lower part of the front of the shaft of the femur: this communicates with a synovial bursa interposed between the tendon and the front of the femur by an orifice of variable size. On each side of the patella the synovial membrane extends beneath the aponeurosis of the Vasti muscles, and more especially beneath that of the Vastus internus. Below the patella it is separated from the anterior ligament by the anterior part of the capsule and a considerable quantity of adipose tissue. In this situation it sends off a triangular prolongation, containing a few ligamentous fibres, which extends from the anterior part of the joint below the patella to the front of the intercondyloid notch. This fold has been termed the *ligamentum mucosum*. It

FIG. 187.—Longitudinal section through the middle of the right knee-joint. (After Braune.)

also sends off two fringe-like folds, called the *ligamenta alaria*, which extend from the sides of the ligamentum mucosum, upward and laterally between the patella and femur. On either side of the joint it passes downward from the femur, lining the capsule to its point of attachment to the semilunar cartilages; it may then be traced over the upper surfaces of these cartilages to their free borders, and from thence along their under surfaces to the tibia. At the back part of the external one it forms a *cul-de-sac* between the groove on its surface and the tendon of the Popliteus; it surrounds the crucial ligaments and lines the inner surface of the ligaments which enclose the joint. The pouch of synovial membrane between the Extensor tendon and front of the femur is supported, during the movements of the knee, by a small muscle, the Subcrureus, which is inserted into the upper part of the capsular ligament.

The folds of synovial membrane and the fatty processes contained in them act, as it seems, mainly as padding to fill up interspaces and obviate concussions. Sometimes the bursa beneath the Quadriceps extensor is completely shut off from the rest of the synovial cavity, thus forming a closed sac between the Quadriceps and the lower part of the front of the femur, or it may communicate with the synovial cavity by a minute aperture.

The bursæ about the knee-joint are the following:

In front there are three bursæ: one is interposed between the patella and the skin; another, of small size, between the upper part of the tuberosity of the tibia and the ligamentum patellæ; and a third between the lower part of the tuberosity of the tibia and the skin. On the outer side there are four bursæ: (1) one beneath the outer head of the Gastrocnemius (which sometimes communicates with the joint); (2) one above the external lateral ligament between it and the tendon of the Biceps; (3) one beneath the external lateral ligament between it and the tendon of the Popliteus (this is sometimes only an expansion from the next bursa); (4) one beneath the tendon of the Popliteus between it and the condyle of the femur, which is almost always an extension from the synovial membrane.

On the inner side there are five bursæ: (1) one beneath the inner head of the Gastrocnemius, which sends a prolongation between the tendons of the Gastrocnemius and Semimembranosus: this bursa often communicates with the joint; (2) one above the internal lateral ligament between it and the tendons of the Sartorius, Gracilis, and Semitendinosus; (3) one beneath the internal lateral ligament between it and the tendon of the Semimembranosus: this is sometimes only an expansion from the next bursa; (4) one beneath the tendon of the Semimembranosus, between it and the head of the tibia; (5) sometimes there is a bursa between the tendons of the Semimembranosus and of the Semitendinosus.

Structures around the Joint.—In front and at the sides, the Quadriceps extensor; on the outer side, the tendons of the Biceps and the Popliteus and the external popliteal nerve; on the inner side, the Sartorius, Gracilis, Semitendinosus, and Semimembranosus; behind, an expansion from the tendon of the Semimembranosus, the popliteal vessels, and the internal popliteal nerve, Popliteus, Plantaris, and inner and outer heads of the Gastrocnemius, some lymphatic glands, and fat.

The *Arteries* supplying the joint are derived from the anastomotica magna branch of the femoral, articular branches of the popliteal, anterior and posterior recurrent branches of the anterior tibial, and descending branch from the external circumflex of the Profunda.

The *Nerves* are derived from the obturator, anterior crural, and external and internal popliteal.

Actions.—The knee-joint permits of movements of flexion and extension, and, in certain positions, of slight rotation inward and outward. The movement of flexion and extension does not, however, take place in a simple, hinge-like manner, as in other joints, but is a complicated movement, consisting of a certain amount of gliding and rotation; so that the same part of one articular surface is not always applied to the same part of the other articular surface, and the axis

of motion is not a fixed one. If the joint is examined while in a condition of extreme flexion, the posterior part of the articular surfaces of the tibia will be found to be in contact with the posterior rounded extremities of the condyles of the femur; and if a simple hinge-like movement were to take place, the axis, round which the revolving movement of the tibia occurs, would be in the back part of the condyle. If the leg is now brought forward into a position of semiflexion, the upper surface of the tibia will be seen to glide over the condyles of the femur, so that the middle part of the articular facets are in contact, and the axis of rotation must therefore have shifted forward to nearer the centre of the condyles. If the leg is now brought into the extended position, a still further gliding takes place and a further shifting forward of the axis of rotation. This is not, however, a simple movement, but is accompanied by a certain amount of rotation outward round a vertical axis drawn through the centre of the head of the tibia. This rotation is due to the greater length of the internal condyle, and to the fact that the anterior portion of its articular surface is inclined obliquely outward. In consequence of this it will be seen that toward the close of the movement of extension—that is to say, just before complete extension is effected—the tibia glides obliquely upward and outward over this oblique surface on the inner condyle, and the leg is therefore necessarily rotated outward. In flexion of the joint the converse of these movements takes place: the tibia glides backward round the end of the femur, and at the commencement of the movement the tibia is directed downward and inward along the oblique curve of the inner condyle, thus causing an inward rotation to the leg.

FIG. 188.—View of the posterior surface of the patella, showing diagrammatically the areas of contact with the femur in different positions of the knee.

During flexion and extension the patella moves on the lower end of the femur, but this movement is not a simple gliding one; for if the articular surface of this bone is examined, it will be found to present on each side of the central vertical ridge two less marked transverse ridges, which divide the surface, except a small portion along the inner border, which is cut off by a slight vertical ridge into six facets (see Fig. 188), and therefore does not present a uniform curved surface, as would be the case if a simple gliding movement took place. These six facets—three on each side of the median vertical ridge—correspond to and denote the parts of the bone respectively in contact with the condyles of the femur during flexion, semiflexion, and extension. In flexion only the upper facets on the patella are in contact with the condyles of the femur; the lower two-thirds of the bone rests upon the mass of fat which occupies the space between the femur and tibia. In the semiflexed position of the joint the middle facets on the patella rest upon the most prominent portion of the condyles, and thus afford greater leverage to the Quadriceps by increasing its distance from the centre of motion. In complete extension the patella is drawn up, so that only the lower facets are in contact with the articular surfaces of the condyles. The narrow strip along the inner border is in contact with the outer aspect of the internal condyle when the leg is fully flexed at the knee-joint. As in the elbow, so it is in the knee—the axis of rotation in flexion and extension is not precisely at right angles to the axis of the bone, but during flexion there is a certain amount of alteration of plane; so that, whereas in flexion the femur and tibia are in the same plane, in extension the one bone forms an angle of about ten degrees with the other. There is, however, this difference between the two extremities: that in the upper, during extension, the humeri are parallel and the bones of the forearm diverge; in the lower, the femora converge below and the tibia are parallel.

In addition to the slight rotation during flexion and extension, the tibia enjoys an independent rotation on the condyles of the femur in certain positions of the joint. This movement takes place between the interarticular fibro-cartilages and

the tibia, whereas the movement of flexion and extension takes place between the interarticular fibro-cartilages and the femur. So that the knee may be said to consist of two joints, separated by the fibro-cartilages: an upper (menisco-femoral), in which flexion and extension take place; and a lower (menisco-tibial), allowing of a certain amount of rotation. This latter movement can only take place in the semiflexed position of the limb, when all the ligaments are relaxed.

During *flexion* the ligamentum patellæ is put upon the stretch, as is also the posterior crucial ligament in extreme flexion. The other ligaments are all relaxed by flexion of the joint, though the relaxation of the anterior crucial ligament is very trifling. Flexion is only checked during life by the contact of the leg with the thigh. In the act of extending the leg upon the thigh the ligamentum patellæ is tightened by the Quadriceps extensor; but when the leg is fully extended, as in the erect posture, the ligament becomes relaxed, so as to allow free lateral movement to the patella, which then rests on the front of the lower end of the femur. The other ligaments, with the exception of the posterior crucial, which is partly relaxed, are all on the stretch. When the limb has been brought into a straight line, extension is checked mainly by the tension of all the ligaments except the posterior crucial and ligamentum patellæ. The movements of *rotation* of which the knee is capable are permitted in the semiflexed condition by the partial relaxation of both crucial ligaments, as well as the lateral ligaments. Rotation inward appears to be limited by the tension of the anterior crucial ligament, and by the interlocking of the two ligaments; but rotation outward does not appear to be checked by either crucial ligament, since they uncross during the execution of this movement, but by the lateral ligaments, especially the internal. The main function of the crucial ligaments is to act as a direct bond of union between the tibia and femur, preventing the former bone from being carried too far backward or forward. Thus the anterior crucial ligament prevents the tibia being carried too far forward by the extensor tendons, and the posterior crucial checks too great movement backward by the flexors. They also assist the lateral ligaments in resisting any lateral bending of the joint. The interarticular cartilages are intended, as it seems, to adapt the surface of the tibia to the shape of the femur to a certain extent, so as to fill up the intervals which would otherwise be left in the varying positions of the joint, and to interrupt the jars which would be so frequently transmitted up the limb in jumping or falls on the feet; also to permit of the two varieties of motion, flexion and extension, and rotation, as explained above. The patella is a great defence to the knee-joint from any injury inflicted in front, and it distributes upon a large and tolerably even surface during kneeling the pressure which would otherwise fall upon the prominent ridges of the condyles; it also affords leverage to the Quadriceps extensor muscle to act upon the tibia; and Mr. Ward has pointed out¹ how this leverage varies in the various positions of the joint, so that the action of the muscles produces velocity at the expense of force in the commencement of extension, and, on the contrary, at the close of extension tends to diminish velocity, and therefore the shock to the ligaments at the moment tension of the structures takes place.

Extension of the leg on the thigh is performed by the Quadriceps extensor; *flexion* by the hamstring muscles, assisted by the Gracilis and Sartorius, and, indirectly, by the Gastrocnemius, Popliteus, and Plantaris; *rotation outward*, by the Biceps; and *rotation inward* by the Popliteus, Semitendinosus, and, to a slight extent, the Semimembranosus, the Sartorius, and the Gracilis.

Surface Form.—The interval between the two bones entering into the formation of the knee-joint can always easily be felt. If the limb is extended, it is situated on a slightly higher level than the apex of the patella; but if the limb is slightly flexed, a knife carried horizontally backward immediately below the apex of the patella would pass directly into the joint. When the knee-joint is distended with fluid, the outline of the synovial membrane at the front of the knee may be fairly well mapped out.

Surgical Anatomy.—From a consideration of the construction of the knee-joint it would at first sight appear to be one of the least secure of any of the joints in the body. It is formed

¹ *Human Osteology*, p. 405.

between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is very considerable; the articular surfaces are but ill adapted to each other, and the range and variety of motion which it enjoys is great. All these circumstances tend to render the articulation very insecure; but, nevertheless, on account of the very powerful ligaments which bind the bones together, the joint is one of the strongest in the body, and dislocation from traumatism is of very rare occurrence. When, on the other hand, the ligaments have been softened or destroyed by disease, partial displacement is very liable to occur, and is frequently brought about by the mere action of the muscles displacing the articular surfaces from each other. The tibia may be dislocated in any direction from the femur—forward, backward, inward, or outward; or a combination of two of these dislocations may occur—that is, the tibia may be dislocated forward and laterally, or backward and laterally; and any of these dislocations may be complete or incomplete. As a rule, however, the antero-posterior dislocations are complete, the lateral ones incomplete.

One or other of the semilunar cartilages may become displaced and nipped between the femur and tibia. The accident is produced by a twist of the leg when the knee is flexed, and is accompanied by a sudden pain and fixation of the knee in a flexed position. The cartilage may be displaced either inward or outward: that is to say, either inward toward the tibial spine, so that the cartilage becomes lodged in the intercondyloid notch; or outward, so that the cartilage projects beyond the margin of the two articular surfaces. Acute synovitis, the result of traumatism or exposure to cold, is very common in the knee, on account of its superficial position. When distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about an inch or more above the trochlear surface of the femur, and extending a little higher under the Vastus internus than the Vastus externus. Occasionally the swelling may extend two inches or more. At the sides of the patella the swelling extends lower at the inner side than it does on the outer side. The lower level of the synovial membrane is just above the level of the upper part of the head of the fibula. In the middle line it covers the upper third of the ligamentum patellæ, being separated from it, however, by the capsule and a pad of fat. Chronic synovitis principally shows itself in the form of pulpy degeneration of the synovial membrane, leading to tubercular arthritis. The reasons why tubercular disease of the knee usually commences in the synovial membrane appear to be the complex and extensive nature of this sac; the extensive vascular supply to it; and the fact that injuries are generally diffused and applied to the front of the joint rather than to the ends of the bones. Syphilitic disease not infrequently attacks the knee-joint. In the hereditary form of the disease it is usually symmetrical, attacking both joints, which become filled with synovial effusion, and is very intractable and difficult of cure. In the tertiary form of the disease gummatous infiltration of the synovial membrane may take place. The knee is one of the joints most commonly affected with osteo-arthritis, and is said to be more frequently the seat of this disease in women than in men. The occurrence of the so-called loose cartilage is almost confined to the knee, though they are occasionally met with in the elbow, and, rarely, in some other joints. Many of them occur in cases of osteo-arthritis, in which calcareous or cartilaginous material is formed in one of the synovial fringes and constitutes the foreign body, and may or may not become detached, in the former case only meriting the usual term, "loose" cartilage. In other cases they have their origin in the exudation of inflammatory lymph, and possibly, in some rare instances, a portion of the articular cartilage or one of the semilunar cartilages becomes detached and constitutes the foreign body.

Genu valgum, or knock-knee, is a common deformity of childhood, in which, owing to changes in and about the joint, the angle between the outer border of the tibia and femur is diminished, so that as the patient stands the two internal condyles of the femora are in contact, but the two internal malleoli of the tibiæ are more or less widely separated from each other. When, however, the knees are flexed to a right angle, the two legs are practically parallel with each other. At the commencement of the disease there is a yielding of the internal lateral ligament and other fibrous structures on the inner side of the joint; as a result of this there is a constant undue pressure of the outer tuberosity of the tibia against the outer condyle of the femur. This extra pressure causes arrest of growth and, possibly, wasting of the outer condyle, and a consequent tendency for the tibia to become separated from the internal condyle. To prevent this the internal condyle becomes depressed; probably, as was first pointed out by Mikulicz, by an increased growth of the lower end of the diaphysis on its inner side, so that the line of the epiphysis becomes oblique instead of transverse to the axis of the bone, with a direction downward and inward.

Excision of the knee-joint is most frequently required for tubercular disease of this articulation, but is also practised in cases of disorganization of the knee after rheumatic fever, pyæmia, etc., in osteo-arthritis, and in ankylosis. It is also occasionally called for in cases of injury, gunshot or otherwise. The operation is best performed either by a horseshoe incision, starting from one condyle, descending as low as the tubercle of the tibia, where it crosses the leg, and is then carried upward to the other condyle; or by a transverse incision across the patella. In this latter incision the patella is either removed or sawn across, and the halves subsequently sutured together. The bones having been cleared, and in those cases where the operation is performed for tubercular disease all pulpy tissue having been carefully removed, the section of the femur is first made. This should never include, in children, more than, at the most, two-thirds of the articular surface, otherwise the epiphyseal cartilage will be involved, with disastrous results as regards the growth of the limb. Afterward a thin slice should be removed from the upper

end of the tibia, not more than half an inch. If any diseased tissue still appears to be left in the bones, it should be removed with the gouge rather than that a further section of the bones should be made.

III. Articulations between the Tibia and Fibula.

The articulations between the tibia and fibula are effected by ligaments which connect both extremities, as well as the shafts of the bones. They may, consequently, be subdivided into three sets: 1. The Superior Tibio-fibular articulation. 2. The Middle Tibio-fibular ligament or interosseous membrane. 3. The Inferior Tibio-fibular articulation.

1. SUPERIOR TIBIO-FIBULAR ARTICULATION.

This articulation is an arthrodial joint. The contiguous surfaces of the bones present two flat, oval facets covered with cartilage, and connected together by the following ligaments:

Capsular.

Anterior Superior Tibio-fibular.

Posterior Superior Tibio-fibular.

The **Capsular Ligament** consists of a membranous bag which surrounds the articulation, being attached around the margins of the articular facets on the tibia and fibula, and is much thicker in front than behind.

The **Anterior Superior Ligament** (Fig. 185) consists of two or three broad and flat bands which pass obliquely upward and inward from the front of the head of the fibula to the front of the outer tuberosity of the tibia.

The **Posterior Superior Ligament** (Fig. 184) is a single thick and broad band which passes upward and inward from the back part of the head of the fibula to the back part of the outer tuberosity of the tibia. It is covered by the tendon of the Popliteus muscle.

A **Synovial Membrane** lines this articulation, which at its upper and back part is occasionally continuous with that of the knee-joint.

2. MIDDLE TIBIO-FIBULAR LIGAMENT OR INTEROSSEOUS MEMBRANE.

An interosseous membrane extends between the contiguous margins of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. It consists of a thin, aponeurotic lamina composed of oblique fibres which for the most part pass downward and outward between the interosseous ridges on the two bones; some few fibres, however, pass in the opposite direction, downward and inward. It is broader above than below. Its upper margin does not quite reach the superior tibio-fibular joint, but presents a free concave border, above which is a large, oval aperture for the passage of the anterior tibial vessels forward to the anterior aspect of the leg. At its lower part is an opening for the passage of the anterior peroneal vessels. It is continuous below with the inferior interosseous ligament, and is perforated in numerous parts for the passage of small vessels. It is in relation, in front, with the Tibialis anticus, Extensor longus digitorum, Extensor proprius hallucis, Peroneus tertius, and the anterior tibial vessels and nerve; behind, with the Tibialis posticus and Flexor longus hallucis.

3. INFERIOR TIBIO-FIBULAR ARTICULATION.

This articulation is formed by the rough, convex surface of the inner side of the lower end of the fibula, connected with a concave rough surface on the outer side of the tibia. Below, to the extent of about two lines, these surfaces are smooth, and covered with cartilage, which is continuous with that of the ankle-joint. The ligaments of this joint are—

Anterior Inferior Tibio-fibular.

Posterior Inferior Tibio-fibular.

Transverse or Inferior.

Inferior Interosseous.

The **Anterior Inferior Ligament** (Fig. 190) is a flat, triangular band of fibres, broader below than above, which extends obliquely downward and outward between the adjacent margins of the tibia and fibula, on the front aspect of the articulation. It is in relation, in front, with the *Peroneus tertius*, the aponeurosis of the leg, and the integument; behind, with the inferior interosseous ligament; and lies in contact with the cartilage covering the astragalus.

The **Posterior Inferior Ligament**, smaller than the preceding, is disposed in a similar manner on the posterior surface of the articulation.

The **Transverse Ligament** or **Inferior Ligament** lies under cover of the posterior ligament, and is a strong, thick band of yellowish fibres which passes transversely across the back of the joint, from the external malleolus to the posterior border of the articular surface of the tibia, almost as far as its malleolar process. This ligament projects below the margin of the bones, and forms part of the articulating surface for the astragalus.

The **Inferior Interosseous Ligament** consists of numerous short, strong, fibrous bands which pass between the contiguous rough surfaces of the tibia and fibula, and constitute the chief bond of union between the bones. This ligament is continuous above with the interosseous membrane.

The **Synovial Membrane** lining the articular surface is derived from that of the ankle-joint.

Actions.—The movement permitted in these articulations is limited to a very slight gliding of the articular surfaces one upon another.

IV. Ankle-joint.

The **Ankle** is a ginglymus or hinge-joint. The bones entering into its formation are the lower extremity of the tibia and its malleolus and the external malleolus of the fibula, which forms a mortise to receive the upper convex surface of the astragalus and its two lateral facets. The bony surfaces are covered with carti-

FIG. 189.—Ankle-joint: tarsal and tarso-metatarsal articulations. Internal view. Right side.

lage and connected together by a capsule, which in places forms thickened bands constituting the following ligaments:

Anterior.
Posterior.

Internal Lateral.
External Lateral.

The **Anterior Ligament** (Fig. 189) is a broad, thin, membranous layer, attached, above, to the anterior margin of the lower extremity of the tibia; below, to the margin of the astragalus, in front of its articular surface. It is in relation, in front, with the Extensor tendons of the toes, with the tendons of the Tibialis anticus and Peroneus tertius, and the anterior tibial vessels and nerve; behind, it lies in contact with the synovial membrane.

The **Posterior Ligament** is very thin, and consists principally of transverse fibres. It is attached, above, to the margin of the articular surface of the tibia, blending with the transverse tibio-fibular ligament; below, to the astragalus, behind its superior articular facet. Externally, where a somewhat thickened band of transverse fibres is attached to the hollow on the inner surface of the external malleolus, it is thicker than internally.

The **Internal Lateral or Deltoid Ligament** is a strong, flat, triangular band, attached, above, to the apex and anterior and posterior borders of the inner malleolus. The most anterior fibres pass forward to be inserted into the navicular bone and the inferior calcaneo-navicular ligament; the middle descend almost perpendicularly to be inserted into the sustentaculum tali of the os calcis; and the posterior fibres pass backward and outward to be attached to the inner side of the astragalus. This ligament is covered by the tendons of the Tibialis posticus and Flexor longus digitorum muscles.

FIG. 190.—Ankle-joint: tarsal and tarso-metatarsal articulations. External view. Right side.

The **External Lateral Ligament** (Fig. 190) consists of three distinctly specialized fasciculi of the capsule, taking different directions and separated by distinct intervals; for which reason it is described by some anatomists as three distinct ligaments.¹

The *anterior fasciculus* (anterior astragalo-fibular), the shortest of the three, passes from the anterior margin of the external malleolus forward and inward to the astragalus, in front of its external articular facet.

The *posterior fasciculus* (posterior astragalo-fibular), the most deeply seated, passes inward from the depression at the inner and back part of the external malleolus to a prominent tubercle on the posterior surface of the astragalus. Its fibres are almost horizontal in direction.

¹ Humphry, *On the Skeleton*, p. 559.

The *middle fasciculus* (calcaneo-fibular), the longest of the three, is a narrow, rounded cord passing from the apex of the external malleolus downward and slightly backward to a tubercle on the outer surface of the os calcis. It is covered by the tendons of the Peroneus longus and brevis.

The **Synovial Membrane** invests the inner surface of the ligaments, and sends a duplicature upward between the lower extremities of the tibia and fibula for a short distance.

Relations.—The tendons, vessels, and nerves in connection with the joint are, in front, from within outward, the Tibialis anticus, Extensor proprius hallucis, anterior tibial vessels, anterior tibial nerve, Extensor longus digitorum, and Peroneus tertius; behind, from within outward, the Tibialis posticus, Flexor longus digitorum, posterior tibial vessels, posterior tibial nerve, Flexor longus hallucis; and, in the groove behind the external malleolus, the tendons of the Peroneus longus and brevis.

The *Arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and the peroneal.

The *Nerves* are derived from the anterior and posterior tibial.

Actions.—The movements of the joint are those of flexion and extension. Flexion consists in the approximation of the dorsum of the foot to the front of the leg, while in extension the heel is drawn up and the toes pointed downward. The malleoli tightly embrace the astragalus in all positions of the joint, so that any slight degree of lateral movement which may exist is simply due to stretching of the inferior tibio-fibular ligaments and slight bending of the shaft of the fibula. Of the ligaments, the internal, or deltoid, is of very great power—so much so that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the middle fasciculus of the external lateral ligament, binds the bones of the leg firmly to the foot and resists displacement in every direction. Its anterior and posterior fibres limit extension and flexion of the foot respectively, and the anterior fibres also limit abduction. The posterior portion of the external lateral ligament assists the middle portion in resisting the displacement of the foot backward, and deepens the cavity for the reception of the astragalus. The anterior fasciculus is a security against the displacement of the foot forward, and limits extension of the joint. The movements of *inversion* and *eversion* of the foot, together with the minute changes in form by which it is applied to the ground or takes hold of an object in climbing, etc., are mainly effected in the tarsal joints, the one which enjoys the greatest amount of motion being that between the astragalus and os calcis behind and the navicular and cuboid in front. This is often called the *transverse* or *medio-tarsal joint*, and it can, with the subordinate joints of the tarsus, replace the ankle-joint in a great measure when the latter has become ankylosed.

Extension of the tarsal bones upon the tibia and fibula is produced by the Gastrocnemius, Soleus, Plantaris, Tibialis posticus, Peroneus longus and brevis, Flexor longus digitorum, and Flexor longus hallucis; *flexion*, by the Tibialis anticus, Peroneus tertius, Extensor longus digitorum, and Extensor proprius hallucis;¹ *inversion*, in the extended position, is produced by the Tibialis anticus and posticus; and *eversion* by the Peronei.

Surface Form.—The line of the ankle-joint may be indicated by a transverse line drawn across the front of the lower part of the leg, about half an inch above the level of the tip of the internal malleolus.

Surgical Anatomy.—Displacement of the trochlear surface of the astragalus from the tibio-fibular mortise is not of common occurrence, as the ankle-joint is a very strong and powerful articulation, and great force is required to produce it. Nevertheless, dislocation does occasionally occur, both in an antero-posterior and a lateral direction. In the latter, which is the most common, fracture is a necessary accompaniment of the injury. The dislocation in these cases is somewhat peculiar, and is not a displacement in a horizontally lateral direction, such as usually

¹ The student must bear in mind that the Extensor longus digitorum and Extensor proprius hallucis are *extensors* of the toes, but *flexors* of the ankle, and that the Flexor longus digitorum and Flexor longus hallucis are *flexors* of the toes, but *extensors* of the ankle.

occurs in lateral dislocations of ginglymoid joints, but the astragalus undergoes a partial rotation round an antero-posterior axis drawn through its own centre, so that the superior surface, instead of being directed upward, is inclined more or less inward or outward according to the variety of the displacement.

The ankle-joint is more frequently sprained than any joint in the body, and this may lead to acute synovitis. In these cases, when the synovial sac is distended with fluid, the bulging appears principally in the front of the joint, beneath the anterior tendons, and on either side, between the *Tibialis anticus* and the internal lateral ligament on the inner side, and between the *Peroneus tertius* and the external lateral ligament on the outer side. In addition to this, bulging frequently occurs posteriorly, and a fluctuating swelling may be detected on either side of the tendo Achillis.

Chronic synovitis may result from frequent sprains, and when once this joint has been sprained it is more liable to a recurrence of the injury than it was before; or it may be tuber-

FIG. 191.—Section of the right foot near its inner border, dividing the tibia, astragalus, navicular, internal cuneiform, and first metatarsal bone, and the first phalanx of the great toe. (After Braune.)

cular in its origin, the disease usually commencing in the astragalus and extending to the joint, though it may commence as a synovitis the result probably of some slight strain in a tubercular subject.

Excision of the ankle-joint is not often performed for two reasons. In the first place, disease of the articulation for which this operation is indicated is frequently associated with disease of the tarsal bones, which prevents its performance; and, secondly, the foot after excision is frequently of very little use; far less, in fact, than after a Symes's amputation, which is often, therefore, a preferable operation in these cases. Excision may, however, be attempted in cases of tubercular arthritis, in a young and otherwise healthy subject, where the disease is limited to the bones forming the joint. It may also be required after injury where the vessels and nerves have not been damaged and the patient is young and free from visceral disease. The excision is best performed by two lateral incisions. One commencing two and a half inches above the external malleolus, carried down the posterior border of the fibula, round the end of the bone, and then forward and downward as far as the calcaneo-cuboid joint, midway between the tip of the external malleolus and the tuberosity on the fifth metatarsal bone. Through this incision the fibula is cleared, the external lateral ligament is divided, and the bone sawn through about half an inch above the level of the ankle-joint and removed. A similar curved incision is now made on the inner side of the foot, commencing two and a half inches above the lower end of the tibia, carried down the posterior border of the bone, round the internal malleolus, and forward and downward to the tuberosity of the navicular bone. Through this incision the tibia is cleared in front and behind, the internal lateral, the anterior and posterior ligaments divided, and the end of the tibia protruded through the wound by displacing the foot outward, and sawn off sufficiently high to secure a healthy section of bone. The articular surface of the astragalus is now to be sawn off or the whole bone removed. In cases where the operation is performed for tubercular arthritis the latter course is probably preferable, as the injury done by the saw is frequently the starting point of fresh caries; and after removal of the whole bone the shortening is not appreciably increased, and the result as regards union appears to be as good as when two sawn surfaces of bone are brought into apposition.

V. Articulations of the Tarsus.

1. ARTICULATIONS OF THE OS CALCIS AND ASTRAGALUS.

The articulations between the os calcis and astragalus are two in number—
anterior and posterior. They are arthrodial joints. The bones are connected
together by four ligaments:

External Calcaneo-astragaloid.
Internal Calcaneo-astragaloid.

Posterior Calcaneo-astragaloid.
Interosseous.

The **External Calcaneo-astragaloid Ligament** (Fig. 190) is a short, strong, fasciculus passing from the outer surface of the astragalus, immediately beneath its external malleolar facet, to the outer surface of the os calcis. It is placed in front of the middle fasciculus of the external lateral ligament of the ankle-joint, with the fibres of which it is parallel.

The **Internal Calcaneo-astragaloid Ligament** is a band of fibres connecting the internal tubercle of the back of the astragalus with the back of the sustentaculum tali. Its fibres blend with those of the inferior calcaneo-navicular ligament.

The **Posterior Calcaneo-astragaloid Ligament** (Fig. 189) connects the external tubercle of the astragalus with the upper and inner part of the os calcis; it is a short band, the fibres of which radiate from their narrow attachment to the astragalus.

The **Interosseous Ligament** forms the chief bond of union between the bones. It consists of numerous vertical and oblique fibres attached by one extremity to the groove between the articulating facets on the under surface of the astragalus; by the other to a corresponding depression on the upper surface of the os calcis. It is very thick and strong, being at least an inch in breadth from side to side, and serves to unite the os calcis and astragalus solidly together.

The **Synovial Membranes** (Fig. 193) are two in number: one for the posterior calcaneo-astragaloid articulation; a second for the anterior calcaneo-astragaloid joint. The latter synovial membrane is continued forward between the contiguous surfaces of the astragalus and navicular bones.

Actions.—The movements permitted between the astragalus and os calcis are limited to a gliding of the one bone on the other in a direction from before backward, and from side to side.

2. ARTICULATIONS OF THE OS CALCIS WITH THE CUBOID.

The ligaments connecting the os calcis with the cuboid are four in number:

Dorsal.	{ Superior Calcaneo-cuboid. Internal Calcaneo-cuboid (Interosseous).
Plantar.	{ Long Calcaneo-cuboid. Short Calcaneo-cuboid.

The **Superior Calcaneo-cuboid Ligament** (Fig. 190) is a thin and narrow fasciculus which passes between the contiguous surfaces of the os calcis and cuboid on the dorsal surface of the joint.

The **Internal Calcaneo-cuboid (Interosseous) Ligament** (Fig. 190) is a short but thick and strong band of fibres arising from the os calcis, in the deep hollow which intervenes between it and the astragalus, and closely blended, at its origin, with the superior calcaneo-navicular ligament. It is inserted into the inner side of the cuboid bone. This ligament forms one of the chief bonds of union between the first and second rows of the tarsus.

The **Long Calcaneo-cuboid (Long Plantar) Ligament** (Fig. 192), the more superficial of the two plantar ligaments, is the longest of all the ligaments of the tarsus: it is attached to the under surface of the os calcis, from near the tuberosities, as far forward as the anterior tubercle; its fibres pass forward to be attached to the ridge on the under surface of the cuboid bone, the more superficial fibres being

continued onward to the bases of the second, third, and fourth metatarsal bones. This ligament crosses the groove on the under surface of the cuboid bone, converting it into a canal for the passage of the tendon of the Peroneus longus.

The **Short Calcaneo-cuboid (Short Plantar) Ligament** lies nearer to the bones than the preceding, from which it is separated by a little areolar tissue. It is exceedingly broad, about an inch in length, and extends from the tubercle and the depression in front of it, on the fore part of the under surface of the os calcis, to the inferior surface of the cuboid bone behind the peroneal groove.

Synovial Membrane.—The synovial membrane in this joint is distinct. It lines the inner surface of the ligaments.

Actions.—The movements permitted between the os calcis and cuboid are limited to a slight gliding upon each other.

3. THE LIGAMENTS CONNECTING THE OS CALCIS AND NAVICULAR.

Though these two bones do not directly articulate, they are connected together by two ligaments:

Superior or External Calcaneo-navicular.

Inferior or Internal Calcaneo-navicular.

The **Superior or External Calcaneo-navicular** (Fig. 190) arises, as already mentioned, with the internal calcaneo-cuboid in the deep hollow between the astragalus and os calcis; it passes forward from the upper surface of the anterior extremity of the os calcis to the outer side of the navicular bone. These two ligaments resemble the letter Y, being blended together behind, but separated in front.

The **Inferior or Internal Calcaneo-navicular** (Fig. 192) is by far the larger and stronger of the two ligaments between these bones; it is a broad and thick band of fibres, which passes forward and inward from the anterior margin of the sustentaculum tali of the os calcis to the under surface of the navicular bone. This ligament not only serves to connect the os calcis and navicular, but supports the head of the astragalus, forming part of the articular cavity in which it is received. The *upper surface* presents a fibro-cartilaginous facet, lined by the synovial membrane continued from the anterior calcaneo-astragaloid articulation, upon which a portion of the head of the astragalus rests. Its *under surface* is in contact with the tendon of the Tibialis posticus muscle;¹ its inner border is blended with the fore part of the Deltoid ligament, thus completing the socket for the head of the astragalus.

FIG. 192.—Ligaments of the plantar surface of the foot.

the disease known as *flat-foot*. This ligament contains a considerable amount of elastic fibre, so as to

¹ Mr. Hancock describes an extension of this ligament upward on the inner side of the foot, which completes the socket of the joint in that direction (*Lancet*, 1866 vol. i., p. 618).

give elasticity to the arch and spring to the foot; hence it is sometimes called the "spring" ligament. It is supported, on its under surface, by the tendon of the *Tibialis posticus*, which spreads out at its insertion into a number of fasciculi which are attached to most of the tarsal and metatarsal bones; this prevents undue stretching of the ligament and is a protection against the occurrence of flat-foot.

4. ARTICULATION OF THE ASTRAGALUS WITH THE NAVICULAR BONE.

The articulation between the astragalus and navicular is an arthrodial joint: the rounded head of the astragalus being received into the concavity formed by the posterior surface of the navicular, the anterior articulating surface of the calcaneum, and the upper surface of the inferior calcaneo-navicular ligament, which fills up the triangular interval between these bones. The only ligament of this joint is the **superior astragalo-navicular**. It is a broad band, which passes obliquely forward from the neck of the astragalus to the superior surface of the navicular bone. It is thin, and weak in texture, and covered by the *Extensor tendons*. The inferior calcaneo-navicular supplies the place of an inferior ligament.

The **Synovial Membrane** which lines the joint is continued forward from the anterior calcaneo-astragaloid articulation.

Actions.—This articulation permits of considerable mobility, but its feebleness is such as to allow occasionally of dislocation of the other bones of the tarsus from the astragalus.

The *transverse tarsal* or *medio-tarsal joint* is formed by the articulation of the os calcis with the cuboid, and by the articulation of the astragalus with the navicular. The movement which takes place in this joint is more extensive than that in the other tarsal joints, and consists of a sort of rotation by means of which the sole of the foot may be slightly flexed and extended or carried inward (inverted) and outward (everted).

5. THE ARTICULATION OF THE NAVICULAR WITH THE CUNEIFORM BONES.

The navicular is connected to the three cuneiform bones by

Dorsal and Plantar ligaments.

The **Dorsal Ligaments** are small, longitudinal bands of fibrous tissue arranged as three bundles, one to each of the cuneiform bones. That bundle of fibres which connects the navicular with the internal cuneiform is continued round the inner side of the articulation to be continuous with the plantar ligament which connects these two bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by processes given off from the tendon of the *Tibialis posticus*.

Actions.—The movements permitted between the navicular and cuneiform bones are limited to a slight gliding upon each other.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

6. THE ARTICULATION OF THE NAVICULAR WITH THE CUBOID.

The navicular bone is connected with the cuboid by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** consists of a band of fibrous tissue which passes obliquely forward and outward from the navicular to the cuboid bone.

The **Plantar Ligament** consists of a band of fibrous tissue which passes nearly transversely between these two bones.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of these two bones.

Actions.—The movements permitted between the navicular and cuboid bones are limited to a slight gliding upon each other.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

7. THE ARTICULATION OF THE CUNEIFORM BONES WITH EACH OTHER.

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligaments** consist of two bands of fibrous tissue which pass transversely, one connecting the internal with the middle cuneiform, and the other connecting the middle with the external cuneiform.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum. They are strengthened by the processes given off from the tendon of the *Tibialis posticus*.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent cuneiform bones.

The **Synovial Membrane** of these joints is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the cuneiform bones are limited to a slight gliding upon each other.

8. THE ARTICULATION OF THE EXTERNAL CUNEIFORM BONE WITH THE CUBOID.

These bones are connected together by

Dorsal, Plantar, and Interosseous ligaments.

The **Dorsal Ligament** consists of a band of fibrous tissue which passes transversely between these two bones.

The **Plantar Ligament** has a similar arrangement. It is strengthened by a process given off from the tendon of the *Tibialis posticus*.

The **Interosseous Ligament** consists of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces of the adjacent sides of these two bones.

The **Synovial Membrane** of this joint is part of the great tarsal synovial membrane.

Actions.—The movements permitted between the external cuneiform and cuboid are limited to a slight gliding upon each other.

Nerve-supply.—All the joints of the tarsus are supplied by the anterior tibial nerve.

Surgical Anatomy.—In spite of the great strength of the ligaments which connect the tarsal bones together, dislocation at some of the tarsal joints does occasionally occur; though, on account of the spongy character of the bones, they are more frequently broken than dislocated, as the result of violence. When dislocation does occur, it is most commonly in connection with the astragalus; for not only may this bone be dislocated from the tibia and fibula at the ankle-joint, but the other bones may be dislocated from it, the trochlear surface of the bone remaining *in situ* in the tibio-fibular mortise. This constitutes what is known as the *subastragaloid* dislocation. Or, again, the astragalus may be dislocated from all its connections—from the tibia and fibula above, the os calcis below, and the navicular in front—and may even undergo a rotation, either on a vertical or horizontal axis. In the former case the long axis of the bone becoming directed across the joint, so that the head faces the articular surface on one or other malleolus; or, in the latter, the lateral surfaces becoming directed upward and downward, so that the trochlear surface faces to one or the other side. Finally, dislocation may occur at the medio-tarsal joint, the anterior tarsal bones being luxated from the astragalus and calcaneum. The other tarsal bones are also, occasionally, though rarely, dislocated from their connections.

VI. Tarso-metatarsal Articulations.

These are arthrodial joints. The bones entering into their formation are four tarsal bones—viz. the internal, middle, and external cuneiform and the cuboid—which articulate with the metatarsal bones of the five toes. The metatarsal bone of the great toe articulates with the internal cuneiform; that of the second is deeply wedged in between the internal and external cuneiform, resting against the middle cuneiform, and being the most strongly articulated of all the metatarsal bones; the third metatarsal articulates with the extremity of the external cunei-

form; the fourth with the cuboid and external cuneiform; and the fifth, with the cuboid. The articular surfaces are covered with cartilage, lined by synovial membrane, and connected together by the following ligaments:

Dorsal. Plantar. Interosseous.

The **Dorsal Ligaments** consist of strong, flat, fibrous bands, which connect the tarsal with the metatarsal bones. The first metatarsal is connected to the internal cuneiform by a single broad, thin, fibrous band; the second has three dorsal ligaments, one from each cuneiform bone; the third has one from the external cuneiform; the fourth has two, one from the external cuneiform and one from the cuboid; and the fifth, one from the cuboid.

The **Plantar Ligaments** consist of longitudinal and oblique fibrous bands connecting the tarsal and metatarsal bones, but disposed with less regularity than on the dorsal surface. Those for the first and second metatarsal are the most strongly marked; the second and third metatarsal receive strong fibrous bands which pass obliquely across from the internal cuneiform; the plantar ligaments of the fourth and fifth metatarsal consist of a few scanty fibres derived from the cuboid.

The **Interosseous Ligaments** are three in number—internal, middle, and external. The *internal* one is the strongest of the three, and passes from the outer extremity of the internal cuneiform to the adjacent angle of the second metatarsal. The *middle* one, less strong than the preceding, connects the external cuneiform with the adjacent angle of the second metatarsal. The *external* interosseous ligament connects the outer angle of the external cuneiform with the adjacent side of the third metatarsal.

The **Synovial Membrane** between the internal cuneiform bone and the first metatarsal bone is a distinct sac. The synovial membrane between the middle and external cuneiform behind, and the second and third metatarsal bones in front, is part of the great tarsal synovial membrane. Two prolongations are sent forward from it—one between the adjacent sides of the second and third metatarsal bones, and one between the third and fourth metatarsal bones. The synovial membrane between the cuboid and the fourth and fifth metatarsal bones is a distinct sac. From it a prolongation is sent forward between the fourth and fifth metatarsal bones.

Actions.—The movements permitted between the tarsal and metatarsal bones are limited to a slight gliding upon each other.

VII. Articulations of the Metatarsal Bones with Each Other.

The base of the first metatarsal bone is not connected with the second metatarsal bone by any ligaments; in this respect it resembles the thumb.

The bases of the four outer metatarsal bones are connected together by dorsal, plantar, and interosseous ligaments.

The **Dorsal Ligaments** consist of bands of fibrous tissue which pass transversely between the adjacent metatarsal bones.

The **Plantar Ligaments** have a similar arrangement to those on the dorsum.

The **Interosseous Ligaments** consist of strong transverse fibres which pass between the rough non-articular portions of the lateral surfaces.

The **Synovial Membrane** between the second and third and the third and fourth metatarsal bones is part of the great tarsal synovial membrane.

The synovial membrane between the fourth and fifth metatarsal bones is a prolongation of the synovial membrane of the cubo-metatarsal joint.

Actions.—The movement permitted in the tarsal ends of the metatarsal bones is limited to a slight gliding of the articular surfaces upon one another.

THE SYNOVIAL MEMBRANES IN THE TARSAL AND METATARSAL JOINTS.

The **Synovial Membranes** (Fig. 193) found in the articulations of the tarsus and metatarsus are six in number: one for the posterior calcaneo-astragaloid

articulation; a second for the anterior calcaneo-astragaloid and astragalo-navicular articulations; a third for the calcaneo-cuboid articulation; and a fourth for the articulations of the navicular with the three cuneiform, the three cuneiform with each other, the external cuneiform with the cuboid, and the middle and external cuneiform with the bases of the second and third metatarsal bones, and the lateral surfaces of the second, third, and fourth metatarsal bones with each other; a fifth for the internal cuneiform with the metatarsal bone of the great toe; and a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial membrane is sometimes found between the contiguous surfaces of the navicular and cuboid bones.

Nerve-supply.—The nerves supplying the tarso-metatarsal joints are derived from the anterior tibial.

The *digital extremities* of all the metatarsal bones are connected together by the *transverse metatarsal ligament*.

The **Transverse Metatarsal Ligament** is a narrow fibrous band which passes transversely across the anterior extremities of all the metatarsal bones, connecting

FIG. 193.—Oblique section of the articulations of the tarsus and metatarsus. Showing the six synovial membranes.

them together. It is blended anteriorly with the plantar (glenoid) ligament of the metatarso-phalangeal articulations. To its posterior border is connected the fascia covering the Interossei muscles. Its inferior surface is concave where the Flexor tendons pass over it. Above it the tendons of the Interossei muscles pass to their insertion. It differs from the transverse metacarpal ligament in that it connects the metatarsal bone of the great toe with the rest of the metatarsal bones.

VIII. Metatarso-phalangeal Articulations.

The metatarso-phalangeal articulations are of the condyloid kind, formed by the reception of the rounded head of the metatarsal bone into a superficial cavity in the extremity of the first phalanx.

The ligaments are—

Plantar.

Two Lateral.

The **Plantar Ligaments** (Glenoid ligaments of Cruveilhier) are thick, dense, fibrous structures. Each is placed on the plantar surface of the joint in the interval between the lateral ligaments, to which they are connected; they are loosely united to the metatarsal bone, but very firmly to the base of the first phalanges. Their plantar surface is intimately blended with the transverse metatarsal ligament, and presents a groove for the passage of the Flexor tendons, the sheath surrounding which is connected to each side of the groove. By their deep

surface they form part of the articular surface for the head of the metatarsal bone, and are lined by a synovial membrane.

The **Lateral Ligaments** are strong, rounded cords, placed one on each side of the joint, each being attached, by one extremity, to the posterior tubercle on the side of the head of the metatarsal bone; and, by the other, to the contiguous extremity of the phalanx.

The **Posterior Ligament** is supplied by the extensor tendon placed over the back of the joint.

Actions.—The movements permitted in the metatarso-phalangeal articulations are flexion, extension, abduction, and adduction.

IX. Articulations of the Phalanges.

The articulations of the phalanges are ginglymus joints.

The ligaments are—

Plantar.

Two Lateral.

The arrangement of these ligaments is similar to those in the metatarso-phalangeal articulations; the extensor tendon supplies the place of a posterior ligament.

Actions.—The only movements permitted in the phalangeal joints are flexion and extension; these movements are more extensive between the first and second phalanges than between the second and third. The movement of flexion is very considerable, but extension is limited by the plantar and lateral ligaments.

Surface Form.—The principal joints which it is necessary to distinguish, with regard to the surgery of the foot, are the medio-tarsal and the tarso-metatarsal joints. The joint between the astragalus and the navicular is best found by means of the tubercle of the navicular bone, for the line of the joint is immediately behind this process. If the foot is grasped and forcibly extended, a rounded prominence, the head of the astragalus, will appear on the inner side of the dorsum in front of the ankle-joint, and if a knife is carried downward, just in front of this prominence and behind the line of the navicular tubercle, it will enter the astragalo-navicular joint. The calcaneo-cuboid joint is situated midway between the external malleolus and the prominent end of the fifth metatarsal bone. The plane of the joint is in the same line as that of the astragalo-navicular. The position of the joint between the fifth metatarsal bone and the cuboid is easily found by the projection of the fifth metatarsal bone, which is the guide to it. The direction of the line of the joint is very oblique, so that, if continued onward, it would pass through the head of the first metatarsal bone. The joint between the fourth metatarsal bone and the cuboid and external cuneiform is the direct continuation inward of the previous joint, but its plane is less oblique; it would be represented by a line drawn from the outer side of the articulation to the middle of the first metatarsal bone. The plane of the joint between the third metatarsal bone and the external cuneiform is almost transverse. It would be represented by a line drawn from the outer side of the joint to the base of the first metatarsal bone. The tarso-metatarsal articulation of the great toe corresponds to a groove which can be felt by making firm pressure on the inner side of the foot one inch in front of the tubercle on the navicular bone; and the joint between the second metatarsal bone and the middle cuneiform is to be found on the dorsum of the foot, half an inch behind the level of the tarso-metatarsal joint of the great toe. The line of the joints between the metatarsal bones and the first phalanges is about an inch behind the webs of the corresponding toes.

THE MUSCLES AND FASCIÆ.¹

THE Muscles are connected with the bones, cartilages, ligaments, and skin, either directly or through the intervention of fibrous structures called tendons or aponeuroses. Where a muscle is attached to bone or cartilage, the fibres terminate in blunt extremities upon the periosteum or perichondrium, and do not come into direct relation with the osseous or cartilaginous tissue. Where muscles are connected with the skin, they either lie as a flattened layer beneath it, or are connected with its areolar tissue by larger or smaller bundles of fibres, as in the muscles of the face.

The muscles vary extremely in their form. In the limbs, they are of considerable length, especially the more superficial ones, the deep ones being generally broad; they surround the bones and form an important protection to the various joints. In the trunk they are broad, flattened, and expanded, forming the parietes of the cavities which they enclose; hence the reason of the terms, *long, broad, short*, etc., used in the description of a muscle.

There is a considerable variation in the arrangement of the fibres of certain muscles with reference to the tendons to which they are attached. In some, the fibres are parallel and run directly from their origin to their insertion; these are quadrilateral muscles, such as the Thyro-hyoid. A modification of these is found in the fusiform muscles, in which the fibres are not quite parallel, but slightly curved, so that the muscle tapers at each end; in their action, however, they resemble the quadrilateral muscles. Secondly, in other muscles the fibres are convergent; arising by a broad origin, they converge to a narrow or pointed insertion. This arrangement of fibres is found in the triangular muscles—*e. g.* the Temporal. In some muscles, which otherwise would belong to the quadrilateral or triangular type, the origin and insertion are not in the same plane, but the plane of the line of origin intersects that of their insertion; such is the case in the Pectineus muscle. Thirdly, in some muscles the fibres are oblique and converge, like the plumes of a pen, to one side of a tendon, which runs the entire length of the muscle. Such a muscle is rhomboidal or penniform, as the Peronei. A modification of these rhomboidal muscles is found in those cases where oblique fibres converge to both sides of a central tendon which runs down the middle of the muscle; these are called bipenniform, and an example is afforded in the Rectus femoris. Finally, we have muscles in which the fibres are arranged in curved bundles in one or more planes, as in the Sphincter muscles. The arrangement of the muscular fibres is of considerable importance in respect to their relative strength and range of movement. Those muscles where the fibres are long and few in number have great range, but diminished strength; where, on the other hand, the fibres are short and more numerous, there is great power, but lessened range.

Muscles differ much in size: the Gastrocnemius forms the chief bulk of the back of the leg, and the fibres of the Sartorius are nearly two feet in length, whilst

¹ The Muscles and Fasciæ are described conjointly, in order that the student may consider the arrangement of the latter in his dissection of the former. It is rare for the student of anatomy in this country to have the opportunity of dissecting the fasciæ separately; and it is for this reason, as well as from the close connection that exists between the muscles and their investing sheaths, that they are considered together. Some general observations are first made on the anatomy of the muscles and fasciæ, the special description being given in connection with the different regions.

the Stapedius, a small muscle of the internal ear, weighs about a grain, and its fibres are not more than two lines in length.

The names applied to the various muscles have been derived—1, from their situation, as the *Tibialis*, *Radialis*, *Ulnaris*, *Peroneus*; 2, from their direction, as the *Rectus abdominis*, *Obliqui capitis*, *Transversalis*; 3, from their uses, as *Flexors*, *Extensors*, *Abductors*, etc.; 4, from their shape, as the *Deltoid*, *Trapezius*, *Rhomboideus*; 5, from the number of their divisions, as the *Biceps*, the *Triceps*; 6, from their points of attachment, as the *Sterno-cleido-mastoid*, *Sterno-hyoid*, *Sterno-thyroid*.

In the description of a muscle the term *origin* is meant to imply its more fixed or central attachment, and the term *insertion*, the movable point to which the force of the muscle is directed; but the origin is absolutely fixed in only a very small number of muscles, such as those of the face, which are attached by one extremity to the bone and by the other to the movable integument; in the greater number the muscle can be made to act from either extremity.

In the dissection of the muscles the student should pay especial attention to the exact *origin*, *insertion*, and *actions* of each, and its more important *relations* with surrounding parts. An accurate knowledge of the points of attachment of the muscles is of great importance in the determination of their action. By a knowledge of the action of the muscles the surgeon is able to explain the causes of displacement in various forms of fracture and the causes which produce distortion in various deformities, and, consequently, to adopt appropriate treatment in each case. The relations, also, of some of the muscles, especially those in immediate apposition with the larger blood-vessels, and the surface-markings they produce, should be especially remembered, as they form useful guides in the application of a ligature to those vessels.

Tendons are white, glistening, fibrous cords, varying in length and thickness, sometimes round, sometimes flattened, of considerable strength, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons presenting in their interior not a trace of them. Nerves also are not present in the smaller tendons, but the larger ones, as the tendo *Achillis*, receive nerves which accompany the nutrient vessels. The tendons consist principally of a substance which yields gelatin.

Aponeuroses are flattened or ribbon-shaped tendons, of a pearly-white color, iridescent, glistening, and similar in structure to the tendons. They are destitute of nerves, and the thicker ones only sparingly supplied with blood-vessels.

The tendons and aponeuroses are connected, on the one hand, with the muscles, and, on the other hand, with the movable structures, as the bones, cartilages, ligaments, fibrous membranes (for instance, the sclerotic). Where the muscular fibres are in a direct line with those of the tendon or aponeurosis, the two are directly continuous, the muscular fibre being distinguishable from that of the tendon only by its striation. But where the muscular fibre joins the tendon or aponeurosis at an oblique angle the former terminates, according to Kölliker, in rounded extremities, which are received into corresponding depressions on the surface of the latter, the connective tissue between the fibres being continuous with that of the tendon. The latter mode of attachment occurs in all the penniform and bipenniform muscles, and in those muscles the tendons of which commence in a membranous form, as the *Gastrocnemius* and *Soleus*.

The *fasciæ* (*fascia*, a bandage) are fibro-areolar or aponeurotic laminæ of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. The *fasciæ* have been subdivided, from the situation in which they are found, into two groups, superficial and deep.

The *superficial fascia* is found immediately beneath the integument over almost the entire surface of the body. It connects the skin with the deep or aponeurotic

fascia, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. In the eyelids and scrotum, where adipose tissue is rarely deposited, this tissue is very liable to serous infiltration. The superficial fascia varies in thickness in different parts of the body: in the groin it is so thick as to be capable of being subdivided in several laminæ. Beneath the fatty layer of the superficial fascia, which is immediately subcutaneous, there is generally another layer of the same structure, comparatively devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves are found, as the superficial epigastric vessels in the abdominal region, the radial and ulnar veins in the forearm, the saphenous veins in the leg and thigh, and the superficial lymphatic glands; certain cutaneous muscles also are situated in the superficial fascia, as the *Platysma myoides* in the neck, and the *Orbicularis palpebrarum* around the eyelids. This fascia is most distinct at the lower part of the abdomen, the scrotum, perinæum, and extremities; is very thin in those regions where muscular fibres are inserted into the integument, as on the side of the neck, the face, and around the margin of the anus. It is very dense in the scalp, in the palms of the hands and soles of the feet, forming a fibro-fatty layer which binds the integument firmly to the subjacent structure.

The superficial fascia connects the skin to the subjacent parts, facilitates the movement of the skin, serves as a soft medium for the passage of vessels and nerves to the integument, and retains the warmth of the body, since the fat contained in its areolæ is a bad conductor of heat.

The *deep fascia* is a dense, inelastic, unyielding fibrous membrane, forming sheaths for the muscles and affording them broad surfaces for attachment. It consists of shining tendinous fibres, placed parallel with one another, and connected together by other fibres disposed in a rectilinear manner. It is usually exposed on the removal of the superficial fascia, forming a strong investment, which not only binds down collectively the muscles in each region, but gives a separate sheath to each, as well as to the vessels and nerves. The fasciæ are thick in unprotected situations, as on the outer side of a limb, and thinner on the inner side. The deep fasciæ assist the muscles in their action by the degree of tension and pressure they make upon their surface; and in certain situations this is increased and regulated by muscular action; as, for instance, by the *Tensor fasciæ femoris* and *Gluteus maximus* in the thigh, by the *Biceps* in the upper and lower extremities, and *Palmaris longus* in the hand. In the limbs the fasciæ not only invest the entire limb, but give off septa which separate the various muscles, and are attached beneath to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

The Muscles and Fasciæ may be arranged, according to the general division of the body, into those of the cranium, face, and neck; those of the trunk; those of the upper extremity; and those of the lower extremity.

MUSCLES AND FASCIÆ OF THE CRANIUM AND FACE.

The muscles of the Cranium and Face consist of ten groups, arranged according to the region in which they are situated:

- | | |
|----------------------|--------------------------------|
| 1. Cranial Region. | 6. Maxillary Region. |
| 2. Auricular Region. | 7. Mandibular Region. |
| 3. Palpebral Region. | 8. Intermaxillary Region. |
| 4. Orbital Region. | 9. Temporo-mandibular Region. |
| 5. Nasal Region. | 10. Pterygo-mandibular Region. |

The muscles contained in each of these groups are the following:

- | | |
|---------------------------|-----------------------------|
| 1. <i>Cranial Region.</i> | 2. <i>Auricular Region.</i> |
| Occipito-frontalis. | Attrahens auriculam. |
| | Attollens auriculam. |
| | Retrahens auriculam. |

3. *Palpebral Region.*

Orbicularis palpebrarum.
Corrugator supercilii.
Tensor tarsi.

4. *Orbital Region.*

Levator palpebræ.
Rectus superior.
Rectus inferior.
Rectus internus.
Rectus externus.
Obliquus superior.
Obliquus inferior.

5. *Nasal Region.*

Pyramidalis nasi.
Levator labii superioris alæque nasi.
Dilatator naris posterior.
Dilatator naris anterior.
Compressor nasi.
Compressor narium minor.
Depressor alæ nasi.

6. *Maxillary Region.*

Levator labii superioris.
Levator anguli oris.
Zygomaticus major.
Zygomaticus minor.

7. *Mandibular Region.*

Levator labii inferioris.
Depressor labii inferioris.
Depressor anguli oris.

8. *Intermaxillary Region.*

Buccinator.
Risorius.
Orbicularis oris.

9. *Temporo-mandibular Region.*

Masseter.
Temporal.

10. *Pterygo-mandibular Region.*

Pterygoideus externus.
Pterygoideus internus.

1. *Cranial Region—Occipito-frontalis.*

Dissection (Fig. 194).—The head being shaved, and a block placed beneath the back of the neck, make a vertical incision through the skin from before backward, commencing at the root of the nose in front, and terminating behind at the occipital protuberance; make

FIG. 194.—Dissection of the head, face, and neck.

a second incision in a horizontal direction along the forehead and round the side of the head, from the anterior to the posterior extremity of the preceding. Raise the skin in front, from the subjacent muscle, from below upward; this must be done with extreme care, removing the integument from the outer surface of the vessels and the nerves which lie immediately beneath the skin.

The Skin of the Scalp.—This is thicker than in any other part of the body. It is intimately adherent to the superficial fascia. The hair-follicles are very closely

set together, and extend throughout the whole thickness of the skin. It also contains a number of sebaceous glands.

The **superficial fascia** in the cranial region is a firm, dense, fibro-fatty layer, intimately adherent to the integument, and to the Occipito-frontalis and its tendi-

FIG. 195.—Muscles of the head, face, and neck.

nous aponeurosis; it is continuous, behind, with the superficial fascia at the back part of the neck; and, laterally, is continued over the temporal fascia. It contains between its layers the superficial vessels and nerves and much granular fat.

The **Occipito-frontalis** (Fig. 195) is a broad musculo-fibrous layer, which covers the whole of one side of the vertex of the skull, from the occiput to the eyebrow. It consists of two muscular slips, separated by an intervening tendinous aponeurosis. The *occipital portion* (sometimes called the *occipitalis* muscle) is thin, quadrilateral in form, and about an inch and a half in length; it arises from the outer two-thirds of the superior curved line of the occipital bone, and from the mastoid portion of the temporal. Its fibres of origin are tendinous, but they soon become

muscular, and ascend in a parallel direction to terminate in a tendinous aponeurosis. The *frontal portion* (sometimes called the *frontalis* muscle) is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader, its fibres are longer, and their structure paler than the occipital portion. Its internal fibres are continuous with those of the *Pyramidalis nasi*. Its middle fibres become blended with the *Corrugator supercilii* and *Orbicularis palpebrarum*; and the outer fibres are also blended with the latter muscle over the external angular process. According to Theile, the innermost fibres are attached to the nasal bones, the outer to the external angular process of the frontal bone. From these attachments the fibres are directed upward, and join the aponeurosis below the coronal suture. The inner margins of the frontal portions of the two muscles are joined together for some distance above the root of the nose; but between the occipital portions there is a considerable, though variable, interval, which is occupied by the aponeurosis.

The **aponeurosis** covers the upper part of the vertex of the skull, being continuous across the middle line with the aponeurosis of the opposite muscle. Behind, it is attached, in the interval between the occipital origins, to the occipital protuberance and highest curved lines of the occipital bone; in front, it forms a short and narrow prolongation between the frontal portions; and on each side it has connected with it the *Attollens* and *Attrahens auriculam* muscles; in this situation it loses its aponeurotic character, and is continued over the temporal fascia to the zygoma as a layer of laminated areolar tissue. This aponeurosis is closely connected to the integument by the firm, dense, fibro-fatty layer which forms the superficial fascia; it is connected with the pericranium by loose cellular tissue, which allows of a considerable degree of movement of the integument.

Nerves.—The frontal portion of the *Occipito-frontalis* is supplied by the facial nerve; its occipital portion by the posterior auricular branch of the facial.

Actions.—The frontal portion of the muscle raises the eyebrows and the skin over the root of the nose, and at the same time draws the scalp forward, throwing the integument of the forehead into transverse wrinkles. The posterior portion draws the scalp backward. By bringing alternately into action the frontal and occipital portions the entire scalp may be moved forward and backward. In the ordinary action of the muscles, the eyebrows are elevated, and at the same time the aponeurosis is fixed by the posterior portion, thus giving to the face the expression of surprise: if the action is more exaggerated, the eyebrows are still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

2. Auricular Region (Fig. 195).

Attrahens auriculam.

Attollens auriculam.

Retrahens auriculam.

These three small muscles are placed immediately beneath the skin around the external ear. In man, in whom the external ear is almost immovable, they are rudimentary. They are the analogues of large and important muscles in some of the mammalia.

Dissection.—This requires considerable care, and should be performed in the following manner: To expose the *Attollens auriculam*, draw the pinna, or broad part of the ear, downward, when a tense band will be felt beneath the skin, passing from the side of the head to the upper part of the concha; by dividing the skin over this band in a direction from below upward, and then reflecting it on each side, the muscle is exposed. To bring into view the *Attrahens auriculam*, draw the helix backward by means of a hook, when the muscle will be made tense, and may be exposed in a similar manner to the preceding. To expose the *Retrahens auriculam*, draw the pinna forward, when the muscle, being made tense, may be felt beneath the skin at its insertion into the back part of the concha, and may be exposed in the same manner as the other muscles.

The *Attrahens auriculam* (*Auricularis anterior*), the smallest of the three, is thin, fan-shaped, and its fibres pale and indistinct; they arise from the lateral

edge of the aponeurosis of the Occipito-frontalis, and converge to be inserted into a projection on the front of the helix.

Relations.—*Superficially*, with the skin; *deeply*, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which are the temporal artery and vein and the temporal fascia.

The **Attollens auriculam** (*Auricularis superior*), the largest of the three, is thin and fan-shaped: its fibres arise from the aponeurosis of the Occipito-frontalis and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the pinna.

Relations.—*Superficially*, with the integument; *deeply*, with the areolar tissue derived from the aponeurosis of the Occipito-frontalis, beneath which is the temporal fascia.

The **Retrahens auriculam** (*Auricularis posterior*) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Relations.—*Superficially*, with the integument; *deeply*, with the mastoid portion of the temporal bone and the posterior auricular artery and nerve.

Nerves.—The Attrahens and Attollens auriculam are supplied by the temporal branch of the facial; the Retrahens auriculam is supplied by the posterior auricular branch of the same nerve.

Actions.—In man, these muscles possess very little action: the Attrahens auriculam draws the ear forward and upward; the Attollens auriculam slightly raises it; and the Retrahens auriculam draws it backward.

3. Palpebral Region (Fig. 195).

Orbicularis palpebrarum.
Corrugator supercilii.

Levator palpebræ.
Tensor tarsi.

Dissection (Fig. 194).—In order to expose the muscles of the face, continue the longitudinal incision made in the dissection of the Occipito-frontalis down the median line of the face to the tip of the nose, and from this point onward to the upper lip; and carry another incision along the margin of the lip to the angle of the mouth, and transversely across the face to the angle of the jaw. Then make an incision in front of the external ear, from the angle of the jaw upward, to join the transverse incision made in exposing the Occipito-frontalis. These incisions include a square-shaped flap, which should be removed in the direction marked in the figure, with care, as the muscles at some points are intimately adherent to the integument.

The **Orbicularis palpebrarum** is a sphincter muscle, which surrounds the circumference of the orbit and eyelids. It arises from the internal angular process of the frontal bone, from the nasal process of the superior maxillary bone in front of the lachrymal groove for the nasal duct, and from the anterior surface and borders of a short tendon, the *tendo oculi*, or *internal tarsal ligament*, placed at the inner angle of the orbit. From this origin the fibres are directed outward, forming a broad, thin, and flat layer, which covers the eyelids, surrounds the circumference of the orbit, and spreads out over the temple and downward on the cheek. The palpebral portion (*ciliaris*) of the Orbicularis is thin and pale; it arises from the bifurcation of the *tendo palpebrarum*, and forms a series of concentric curves, which are on the outer side of the eyelids inserted into the external tarsal ligament. The orbital portion (*orbicularis latus*) is thicker and of a reddish color: its fibres are well developed, and form complete ellipses. The upper fibres of this portion blend with the Occipito-frontalis and Corrugator supercilii.

Relations.—By its *superficial surface*, with the integument. By its *deep surface*, above, with the Occipito-frontalis and Corrugator supercilii, with which it is intimately blended, and with the supra-orbital vessels and nerve; below, it covers the lachrymal sac, and the origin of the Levator labii superioris alæque nasi, the Levator labii superioris, and the Zygomaticus minor muscles. *Internally*, it is occasionally blended with the Pyramidalis nasi. *Externally*, it lies on the temporal

fascia. On the eyelids it is separated from the conjunctiva by the Levator palpebræ, the tarsal ligaments, the tarsal plates, and the Meibomian glands.

The *tendo oculi* (internal tarsal ligament) is a short tendon, about two lines in length and one in breadth, attached to the nasal process of the superior maxillary bone in front of the lachrymal groove. Crossing the lachrymal sac, it divides into two parts, each division being attached to the inner extremity of the corresponding tarsal plate. As the tendon crosses the lachrymal sac, a strong aponeurotic lamina is given off from the posterior surface, which expands over the sac, and is attached to the ridge on the lachrymal bone. This is the reflected aponeurosis of the *tendo oculi*.

The *external tarsal ligament* is a much weaker structure than the *tendo oculi*. It is attached to the margin of the frontal process of the malar bone, and passes inward to the outer commissure of the eyelids; it connects together the outer extremities of the two tarsal cartilages.

Use of Tendo oculi.—Besides giving attachment to part of the Orbicularis palpebrarum and to the tarsal plates, it serves to suck the tears into the lachrymal sac, by its attachment to the sac. Thus, each time the eyelids are closed, the *tendo oculi* becomes tightened, through the action of the Orbicularis, and draws the wall of the lachrymal sac outward and forward, so that a vacuum is made in the sac, and the tears are sucked along the lachrymal canals into it.

The *Corrugator supercilii* is a small, narrow, pyramidal muscle, placed at the inner extremity of the eyebrow, beneath the Occipito-frontalis and Orbicularis palpebrarum muscles. It arises from the inner extremity of the superciliary ridge, from whence its fibres pass upward and outward, and, passing between the palpebral and orbital portions of the Orbicularis palpebrarum, are inserted into the deep surface of the skin, opposite the middle of the orbital arch.

FIG. 196.—Horner's muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations.—By its *anterior surface* with the Occipito-frontalis and Orbicularis palpebrarum muscles; by its *posterior surface*, with the frontal bone and supratrochlear nerve.

The Levator palpebræ will be described with the muscles of the orbital region.

The *Tensor tarsi* (Horner's muscle) (Fig. 196) is a small thin muscle about three lines in breadth and six in length, situated at the inner side of the orbit, behind the *tendo oculi*. It arises from the crest and adjacent part of the orbital surface of the lachrymal bone, and,

passing across the lachrymal sac, divides into two slips, which cover the lachrymal canals and are inserted into the tarsal plates internal to the puncta lachrymalia. Its fibres appear to be continuous with those of the palpebral portion of the Orbicularis palpebrarum; it is occasionally very indistinct.

Nerves.—The Orbicularis palpebrarum, Corrugator supercilii, and Tensor tarsi are supplied by the facial nerve. Recent investigations tend to show that the Orbicularis palpebrarum, Corrugator supercilii, and frontal part of the Occipito-frontalis are in reality supplied by fibres of the third nerve, which descend through the pons varolii to join the facial nerve.

Actions.—The Orbicularis palpebrarum is the sphincter muscle of the eyelids.

The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking; the orbicular portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn inward toward the inner angle of the orbit, and the eyelids are firmly closed as in photophobia. When the skin of the forehead, temple, and cheek is thus drawn inward by the action of the muscle it is thrown into folds, especially radiating from the outer angle of the eyelids, which give rise in old age to the so-called "crow's feet." The Levator palpebræ is the direct antagonist of this muscle; it raises the upper eyelid and exposes the globe. The Corrugator supercilii draws the eyebrow downward and inward, producing the vertical wrinkles of the forehead. It is the "frowning" muscle, and may be regarded as the principal agent in the expression of suffering. The Tensor tarsi draws the eyelids and the extremities of the lachrymal canals inward and compresses them against the surface of the globe of the eye; thus placing them in the most favorable situation for receiving the tears. It serves, also, to compress the lachrymal sac.

4. Orbital Region (Fig. 197).

Levator palpebræ superioris.	Rectus internus.
Rectus superior.	Rectus externus.
Rectus inferior.	Obliquus oculi superior.
Obliquus oculi inferior.	

Dissection.—To open the cavity of the orbit, remove the skull-cap and brain; then saw through the frontal bone at the inner extremity of the supraorbital ridge, and externally at its

FIG. 197.—Muscles of the right orbit.

junction with the malar. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the Obliquus superior. When the fragments are cleared away, the periosteum of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onward into the globe; insert the point of a blowpipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature round the nerve so as to prevent the air escaping. The globe being now drawn forward, the muscles will be put upon the stretch.

The Levator palpebræ superioris is thin, flat, and triangular in shape. It arises from the under surface of the lesser wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Superior rectus. At its origin it is narrow and tendinous, but soon becomes broad and

fleshy, and finally terminates in a wide aponeurosis, which is inserted into the upper margin of the superior tarsal plate. From this aponeurosis a thin expansion is continued onward, passing between the fibres of the Orbicularis to be inserted into the skin of the lid, and some deeper fibres blend with an expansion from the sheath of the Superior rectus muscle, and are with it prolonged into the conjunctiva.

Relations.—By its *upper surface*, with the frontal nerve and supraorbital artery, the periosteum of the orbit and lachrymal gland; and, in the lid, with the inner surface of the tarsal ligament; by its *under surface*, with the Superior rectus, and, in the lid, with the conjunctiva. A small branch of the third nerve enters its under surface.

The **Superior rectus**, the thinnest and narrowest of the four Recti, arises from the upper margin of the optic foramen beneath the Levator palpebræ, and from the fibrous sheath of the optic nerve; and is inserted by a tendinous expansion into the sclerotic coat, about three or four lines from the margin of the cornea.

Relations.—By its *upper surface*, with the Levator palpebræ; by its *under surface*, with the optic nerve, the ophthalmic artery, the nasal nerve, and the branch of the third nerve which supplies it; and, in front, with the tendon of the Superior oblique and the globe of the eye.

The **Inferior and Internal Recti** arise by a common tendon (the *ligament of Zinn*),¹ which is attached round the circumference of the optic foramen, except at its upper and outer part. The **External rectus** has two heads: the upper one arises from the outer margin of the optic foramen immediately beneath the Superior rectus; the lower head, partly from the ligament of Zinn and partly from a small

pointed process of bone on the lower margin of the sphenoidal fissure. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion (the *tunica albuginea*) into the sclerotic coat, about three or four lines from the margin of the cornea. Between the two heads of the **External rectus** is a narrow interval, through which passes the third, the nasal branch of the ophthalmic division of the fifth and sixth nerves, and the ophthalmic vein. Although nearly all of these muscles present a common origin and are inserted in a similar manner into the sclerotic coat, there are certain differences to be observed in them as regards their length and breadth. The **Internal rectus** is the broadest, the **External** is the longest, and the **Superior** is the thinnest and narrowest.

The **Superior oblique** is a fusiform muscle placed at the upper and inner side of the orbit, internal to the Levator palpebræ. It arises about a line above the inner margin of the optic foramen, and, passing forward to the inner angle of the orbit, terminates in a rounded tendon, which plays in a ring or pulley formed by cartilaginous tissue attached to a depression beneath the internal angular process of the frontal bone, the contiguous surfaces of the tendon and ring being lined by a delicate synovial membrane and enclosed in a thin fibrous investment. The tendon is reflected backward, outward, and downward beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into the sclerotic coat,

The **Superior oblique** is a fusiform muscle placed at the upper and inner side of the orbit, internal to the Levator palpebræ. It arises about a line above the inner margin of the optic foramen, and, passing forward to the inner angle of the orbit, terminates in a rounded tendon, which plays in a ring or pulley formed by cartilaginous tissue attached to a depression beneath the internal angular process of the frontal bone, the contiguous surfaces of the tendon and ring being lined by a delicate synovial membrane and enclosed in a thin fibrous investment. The tendon is reflected backward, outward, and downward beneath the Superior rectus to the outer part of the globe of the eye, and is inserted into the sclerotic coat,

¹ The ligament of Zinn ought, perhaps more appropriately, to be termed the *aponeurosis* or *tendon* of Zinn. Mr. C. B. Lockwood has described a somewhat similar structure on the under surface of the Superior rectus muscle, which is attached to the lesser wing of the sphenoid, forming the upper and outer margin of the optic foramen. This *superior tendon* gives origin to the Superior rectus, the superior head of the External rectus, and the upper part of the Internal rectus. (*Journal of Anatomy and Physiology*, vol. xx. part i. p. 1.)

FIG. 198.—The relative position and attachment of the muscles of the left eyeball.

behind the equator of the eyeball, the insertion of the muscle lying between the Superior and External recti.

Relations.—By its *upper surface*, with the periosteum covering the roof of the orbit and the fourth nerve: the tendon, where it lies on the globe of the eye, is covered by the Superior rectus; by its *under surface*, with the nasal nerve, ethmoidal arteries, and the upper border of the internal rectus.

The **Inferior oblique** is a thin, narrow muscle placed near the anterior margin of the orbit. It arises from a depression on the orbital plate of the superior maxillary bone, external to the lachrymal groove. Passing outward, backward, and upward between the Inferior rectus and the floor of the orbit, and then between the eyeball and the External rectus, it is inserted into the outer part of the sclerotic coat between the Superior and External recti, near to, but somewhat behind, the tendon of insertion of the Superior oblique.

Relations.—By its *ocular surface*, with the globe of the eye and with the Inferior rectus; by its *orbital surface*, with the periosteum covering the floor of the orbit, and with the External rectus. Its borders look forward and backward; the posterior one receives a branch of the third nerve.

Nerves.—The Levator palpebræ, Inferior oblique, and all the Recti excepting the External, are supplied by the third nerve; the Superior oblique, by the fourth; the External rectus, by the sixth.

Actions.—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis palpebrarum. The four Recti muscles are attached in such a manner to the globe of the eye that, acting singly, they will turn it either upward, downward, inward, or outward, as expressed by their names. The movement produced by the Superior or Inferior rectus is not quite a simple one, for, inasmuch as they pass obliquely outward and forward to the eyeball, the elevation or depression of the cornea must be accompanied by a certain deviation inward, with a slight amount of rotation, which, however, is corrected by the Oblique muscles, the Inferior oblique correcting the deviation inward of the Superior rectus, and the Superior oblique that of the Inferior rectus. The contraction of the External and Internal recti, on the other hand, produces a purely horizontal movement. If any two contiguous recti of one eye act together, they carry the globe of the eye in the diagonal of these directions—viz. upward and inward, upward and outward, downward and inward, or downward and outward. The movement of circumduction, as in looking round a room, is performed by the alternate action of the four Recti. The Oblique muscles rotate the eyeball on its *antero-posterior axis*, this kind of movement being required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of each eye.¹

Fasciæ of the Orbit.—The connective tissue of the orbit is in various places condensed into thin membranous layers, which may be conveniently described as (1) the orbital fascia; (2) the sheath of the muscles; and (3) the covering of the eyeball.

(1) The *orbital fascia*. This forms the periosteum of the orbit. It is loosely connected to the bones, from which it can be readily separated. Behind, it is connected with the dura mater by processes which pass through the optic foramen and sphenoidal fissure, and with the sheath of the optic nerve. In front it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the palpebral fascia. From its internal surface two processes are given off—one to enclose the lachrymal gland, the other to hold the pulley of the Superior oblique muscle in position.

(2) The sheaths of the muscles give off expansions to the margins of the orbit which limit the action of the muscles.

¹ "On the Oblique Muscles of the Eye in Man and Vertebrate Animals," by John Struthers, M. D., in *Anatomical and Physiological Observations*. For a fuller account of the various co-ordinate actions of the muscles of a single eye and of both eyes than our space allows, the reader may be referred to Dr. M. Foster's *Text-book of Physiology*.

(3) The fascia covering the eyeball—Tenon's capsule—will be described in the sequel.

Surgical Anatomy.—The position and exact point of insertion of the tendons of the Internal and External recti muscles into the globe should be carefully examined from the front of the eyeball, as the surgeon is often required to divide the one or the other muscle for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned inward, requiring the division of the Internal rectus. In the divergent form, which is more rare, the eye is turned outward, the External rectus being especially implicated. The deformity produced in either case is to be remedied by division of one or the other muscle. The operation is thus performed: The lids are to be well separated; the eyeball being rotated outward or inward, the conjunctiva should be raised by a pair of forceps and divided immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclerotic; the submucous areolar tissue is then divided, and into the small aperture thus made a blunt hook is passed upward between the muscle and the globe, and the tendon of the muscle and conjunctiva covering it divided by a pair of blunt-pointed scissors. Or the tendon may be divided by a subconjunctival incision, one blade of the scissors being passed upward between the tendon and the conjunctiva, and the other between the tendon and the sclerotic. The student, when dissecting these muscles, should remove on one side of the subject the conjunctiva from the front of the eye, in order to see more accurately the position of the tendons, while on the opposite side the operation may be performed.

5. Nasal Region (Fig. 195).

Pyramidalis nasi.

Levator labii superioris alæque nasi.

Dilatator naris posterior.

Dilatator naris anterior.

Compressor nasi.

Compressor narium minor.

Depressor alæ nasi.

The **Pyramidalis nasi** is a small pyramidal slip placed over the nasal bone. Its origin is by tendinous fibres from the fascia covering the lower part of the nasal bone and upper part of the cartilage, where it blends with the **Compressor nasi**, and it is inserted into the skin over the lower part of the forehead between the two eyebrows, its fibres decussating with those of the **Occipito-frontalis**.

Relations.—By its *upper surface*, with the skin; by its *under surface*, with the frontal and nasal bones.

The **Levator labii superioris alæque nasi** is a thin triangular muscle placed by the side of the nose, and extending between the inner margin of the orbit and upper lip. It arises by a pointed extremity from the upper part of the nasal process of the superior maxillary bone, and, passing obliquely downward and outward, divides into two slips, one of which is inserted into the cartilage of the ala of the nose; the other is prolonged into the upper lip, becoming blended with the **Orbicularis oris** and **Levator labii superioris proprius**.

Relations.—In front, with the integument, and with a small part of the **Orbicularis palpebrarum** above.

The **Dilatator naris posterior** is a small muscle which is placed partly beneath the elevator of the nose and lip. It arises from the margin of the nasal notch of the superior maxilla and from the sesamoid cartilages, and is inserted into the skin near the margin of the nostril.

The **Dilatator naris anterior** is a thin delicate fasciculus passing from the cartilage of the ala of the nose to the integument near its margin. This muscle is situated in front of the preceding.

The **Compressor nasi** is a small, thin, triangular muscle arising by its apex from the superior maxillary bone, above and a little external to the incisive fossa; its fibres proceed upward and inward, expanding into a thin aponeurosis which is attached to the fibro-cartilage of the nose and is continuous on the bridge of the nose with that of the muscle of the opposite side and with the aponeurosis of the **Pyramidalis nasi**.

The **Compressor narium minor** is a small muscle attached by one end to the alar cartilage, and by the other to the integument at the end of the nose.

The **Depressor alæ nasi** is a short radiated muscle arising from the incisive fossa of the superior maxilla; its fibres ascend to be inserted into the septum and

back part of the ala of the nose. This muscle lies between the mucous membrane and muscular structure of the lip.

Nerves.—All the muscles of this group are supplied by the facial nerve.

Actions.—The *Pyramidalis nasi* draws down the inner angle of the eyebrows and produces transverse wrinkles over the bridge of the nose. The *Levator labii superioris alæque nasi* draws upward the upper lip and ala of the nose: its most important action is upon the nose, which it dilates to a considerable extent. The action of this muscle produces a marked influence over the countenance, and it is the principal agent in the expression of contempt and disdain. The two *Dilatores nasi* enlarge the aperture of the nose. Their action in ordinary breathing is to resist the tendency of the nostrils to close from atmospheric pressure, but in difficult breathing they may be noticed to be in violent action, as well as in some emotions, as anger. The *Depressor alæ nasi* is a direct antagonist of the other muscles of the nose, drawing the ala of the nose downward, and thereby constricting the aperture of the nares. The *Compressor nasi* depresses the cartilaginous part of the nose and compresses the alæ together.

6. Superior Maxillary Region (Fig. 195).

Levator labii superioris.

Zygomaticus major.

Levator anguli oris.

Zygomaticus minor.

The *Levator labii superioris (proprius)* is a thin muscle of a quadrilateral form. It arises from the lower margin of the orbit immediately above the infraorbital foramen, some of its fibres being attached to the superior maxilla, others to the malar bone; its fibres converge to be inserted into the muscular substance of the upper lip.

Relations.—By its *superficial surface* above, with the lower segment of the *Orbicularis palpebrarum*; below, it is subcutaneous. By its *deep surface* it conceals the origin of the *Compressor nasi* and *Levator anguli oris* muscles, and the infraorbital vessels and nerve, as they escape from the infraorbital foramen.

The *Levator anguli oris* arises from the canine fossa immediately below the infraorbital foramen; its fibres incline downward and a little outward, to be inserted into the angle of the mouth, intermingling with those of the *Zygomaticus major*, the *Depressor anguli oris*, and the *Orbicularis*.

Relations.—By its *superficial surface*, with the *Levator labii superioris* and the infraorbital vessels and nerves; by its *deep surface*, with the superior maxilla, the *Buccinator*, and the mucous membrane.

The *Zygomaticus major* is a slender fasciculus which arises from the malar bone, in front of the zygomatic suture, and, descending obliquely downward and inward, is inserted into the angle of the mouth, where it blends with the fibres of the *Levator anguli oris*, the *Orbicularis oris*, and the *Depressor anguli oris*.

Relations.—By its *superficial surface*, with the subcutaneous adipose tissue; by its *deep surface*, with the *Masseter* and *Buccinator* muscles and the facial artery and vein.

The *Zygomaticus minor* arises from the malar bone immediately behind the maxillary suture, and, passing downward and inward, is continuous with the *Orbicularis oris* at the outer margin of the *Levator labii superioris*. It lies in front of the preceding.

Relations.—By its *superficial surface*, with the integument and the *Orbicularis palpebrarum* above; by its *deep surface*, with the *Masseter*, *Buccinator*, and *Levator anguli oris*, and the facial artery and vein.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The *Levator labii superioris* is the proper elevator of the upper lip, carrying it at the same time a little forward. It assists in forming the naso-labial ridge, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness. The *Levator anguli oris* raises the angle of the mouth,

and assists the Levator labii superioris in producing the naso-labial ridge. The Zygomaticus major draws the angle of the mouth backward and upward, as in laughing; whilst the Zygomaticus minor, being inserted into the outer part of the upper lip and not into the angle of the mouth, draws it backward, upward, and outward, and thus gives to the face an expression of sadness.

7. Inferior Maxillary Region (Fig. 195).

Levator labii inferioris (Levator menti).

Depressor labii inferioris (Quadratus menti).

Depressor anguli oris (Triangularis menti).

Dissection.—The muscles in this region may be dissected by making a vertical incision through the integument from the margin of the lower lip to the chin: a second incision should then be carried along the margin of the lower jaw as far as the angle, and the integument carefully removed in the direction shown in Fig. 194.

The Levator labii inferioris (Levator menti) is to be dissected by everting the lower lip and raising the mucous membrane. It is a small conical fasciculus placed on the side of the frænum of the lower lip. It arises from the incisive fossa, external to the symphysis of the lower jaw; its fibres descend to be inserted into the integument of the chin.

Relation.—On its *inner surface*, with the mucous membrane; in the *median line*, it is blended with the muscle of the opposite side; and on its *outer side*, with the Depressor labii inferioris.

The Depressor labii inferioris (Quadratus menti) is a small quadrilateral muscle. It arises from the external oblique line of the lower jaw, between the symphysis and mental foramen, and passes obliquely upward and inward, to be inserted into the integument of the lower lip, its fibres blending with the Orbicularis oris and with those of its fellow of the opposite side. It is continuous with the fibres of the Platysma at its origin. This muscle contains much yellow fat intermingled with its fibres.

Relations.—By its *superficial surface*, with part of the Depressor anguli oris and with the integument, to which it is closely connected; by its *deep surface*, with the mental vessels and nerves, the mucous membrane of the lower lip, the labial glands, and the Levator menti, with which it is intimately united.

The Depressor anguli oris (Triangularis menti) is triangular in shape, arising, by its broad base, from the external oblique line of the lower jaw, from whence its fibres pass upward, to be inserted, by a narrow fasciculus, into the angle of the mouth. It is continuous with the Platysma at its origin and with the Orbicularis oris and Risorius at its insertion, and some of its fibres are directly continuous with those of the Levator anguli oris.

Relations.—By its *superficial surface*, with the integument; by its *deep surface*, with the Depressor labii inferioris and Buccinator.

Nerves.—This group of muscles is supplied by the facial nerve.

Actions.—The Levator labii inferioris raises the lower lip and protrudes it forward, and at the same time wrinkles the integument of the chin, expressing doubt or disdain. The Depressor labii inferioris draws the lower lip directly downward and a little outward, as in the expression of irony. The Depressor anguli oris depresses the angle of the mouth, being the antagonist to the Levator anguli oris and Zygomaticus major; acting with these muscles, it will draw the angle of the mouth directly backward.

8. Intermaxillary Region.

Orbicularis oris.

Buccinator.

Risorius.

Dissection.—The dissection of these muscles may be considerably facilitated by filling the cavity of the mouth with tow, so as to distend the cheeks and lips; the mouth should then be closed by a few stitches and the integument carefully removed from the surface.

The Orbicularis oris (Fig. 195) is not a sphincter muscle, like the Orbicularis

palpebrarum, but consists of numerous strata of muscular fibres, having different directions, which surround the orifice of the mouth. These fibres are partially derived from the other facial muscles which are inserted into the lips, and are partly fibres proper to the lips themselves. Of the former, a considerable number are derived from the Buccinator and form the deeper stratum of the Orbicularis. Some of them—namely, those near the middle of the muscle—decussate at the angle of the mouth, those arising from the upper jaw passing to the lower lip, and those from the lower jaw to the upper lip. Other fibres of the muscle, situated at its upper and lower part, pass across the lips from side to side without decussation. Superficial to this stratum is a second, formed by the Levator and Depressor anguli oris, which cross each other at the angle of the mouth, those from the Depressor passing to the upper lip, and those from the Levator to the lower lip, along which they run to be inserted into the skin near the median line. In addition to these there are fibres from the other muscles inserted into the lips—the Levator labii superioris, the Levator labii superioris alæque nasi, the Zygomatici, and the Depressor labii inferioris; these intermingle with the transverse fibres above described, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the under surface of the skin to the mucous membrane through the thickness of the lip. And in addition to these are fibres by which the muscle is connected directly with the maxillary bones and the septum of the nose. These consist, in the upper lip, of four bands, two of which (*Musculus incisivus superior*) arise from the alveolar border of the superior maxilla, opposite the lateral incisor tooth, and, arching outward on each side, are continuous at the angles of the mouth with the other muscles inserted into this part. The two remaining muscular slips, called the *Naso-labialis*, connect the upper lip to the back of the septum of the nose: as they descend from the septum an interval is left between them. It is this interval which forms the depression seen on the surface of the skin beneath the septum of the nose. The additional fibres for the lower segment (*Musculus incisivus inferior*) arise from the inferior maxilla, externally to the Levator labii inferioris, and arch outward to the angles of the mouth, to join the Buccinator and the other muscles attached to this part.

Relations.—By its *superficial surface*, with the integument, to which it is closely connected; by its *deep surface*, with the buccal mucous membrane, the labial glands, and coronary vessels; by its *outer circumference* it is blended with the numerous muscles which converge to the mouth from various parts of the face. Its *inner circumference* is free, and covered by the mucous membrane.

The **Buccinator** (Fig. 208) is a broad, thin muscle, quadrilateral in form, which occupies the interval between the jaws at the side of the face. It arises from the outer surface of the alveolar processes of the upper and lower jaws, corresponding to the three molar teeth, and, behind, from the anterior border of the pterygo-maxillary ligament. The fibres converge toward the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and those from above with the inferior segment; the highest and lowest fibres continue forward uninterruptedly into the corresponding segment of the lip, without decussation.

Relations.—By its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the lower jaw, the Masseter, and a small portion of the Temporal muscle; anteriorly, with the Zygomatici, Risorius, Levator anguli oris, Depressor anguli oris, and Stenson's duct, which pierces it opposite the second molar tooth of the upper jaw; the facial artery and vein cross it from below upward; it is also crossed by the branches of the facial and buccal nerves; by its *internal surface*, with the buccal glands and mucous membrane of the mouth.

The *pterygo-maxillary ligament* separates the Buccinator muscle from the Superior constrictor of the pharynx. It is a tendinous band, attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the internal oblique line of the lower jaw. Its *inner surface*

corresponds to the cavity of the mouth, and is lined by mucous membrane. Its *outer surface* is separated from the ramus of the jaw by a quantity of adipose tissue. Its *posterior border* gives attachment to the Superior constrictor of the pharynx; its *anterior border*, to the fibres of the Buccinator (see Fig. 208).

The **Risorius** (**Santorini**) (Fig. 195) consists of a narrow bundle of fibres which arises in the fascia over the Masseter muscle, and, passing horizontally forward, is inserted into the skin at the angle of the mouth. It is placed superficial to the Platysma, and is broadest at its outer extremity. This muscle varies much in its size and form.

Nerves.—The muscles in this group are all supplied by the facial nerve. The buccal branch of the inferior maxillary nerve pierces the Buccinator muscle, and by some anatomists is regarded as partly supplying this muscle. Probably it merely pierces it on its way to the mucous membrane of the cheek.

Actions.—The Orbicularis oris in its ordinary action produces the direct closure of the lips; by its deep fibres, assisted by the oblique ones, it closely applies the lips to the alveolar arch. The superficial part, consisting principally of the decussating fibres, brings the lips together and also protrudes them forward. The Buccinators contract and compress the cheeks, so that, during the process of mastication, the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinator muscles expel it from between the lips, as in blowing a trumpet. Hence the name (*buccina*, a trumpet). The Risorius retracts the angles of the mouth, and produces the unpleasant expression which is sometimes seen in tetanus, and is known as “*risus sardonius*.”

9. Temporo-mandibular Region.

Masseter.

Temporal.

Masseteric Fascia.—Covering the Masseter muscle, and firmly connected with it, is a strong layer of fascia derived from the deep cervical fascia. Above, this fascia is attached to the lower border of the zygoma, and, behind, it covers the parotid gland, constituting the *parotid fascia*.

The **Masseter** is exposed by the removal of this fascia (Fig. 195); it is a short, thick muscle, somewhat quadrilateral in form, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a thick, tendinous aponeurosis from the malar process of the superior maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch: its fibres pass downward and backward, to be inserted into the angle and lower half of the outer surface of the ramus of the jaw. The *deep portion* is much smaller and more muscular in texture; it arises from the posterior third of the lower border and the whole of the inner surface of the zygomatic arch; its fibres pass downward and forward, to be inserted into the upper half of the ramus and outer surface of the coronoid process of the jaw. The deep portion of the muscle is partly concealed, in front by the superficial portion; behind, it is covered by the parotid gland. The fibres of the two portions are united at their insertion.

Relations.—By its *superficial surface*, with the Zygomatici, the parotid gland and Socia parotidis, and Stenson's duct; the branches of the facial nerve and the transverse facial vessels, which cross it; the masseteric fascia; the Risorius, Santorini, Platysma myoides, and the integument; by its *deep surface*, with the Temporal muscle at its insertion, the ramus of the jaw, the Buccinator and the long buccal nerve, from which it is separated by a mass of fat. The masseteric nerve and artery enter in on its under surface. Its *posterior margin* is overlapped by the parotid gland. Its *anterior margin* projects over the Buccinator muscle, and the facial vein lies on it below.

The *temporal fascia* is seen, at this stage of the dissection, covering in the Temporal muscle. It is a strong, fibrous investment, covered, on its outer surface, by the Attrahens and Attollens auriculam muscles, the aponeurosis of the Occipito-

frontalis, and by part of the Orbicularis palpebrarum. The temporal vessels and the auriculo-temporal nerve cross it from below upward. Above, it is a single layer, attached to the entire extent of the upper temporal ridge; but below, where it is attached to the zygoma, it consists of two layers, one of which is inserted into the outer, and the other into the inner, border of the zygomatic arch. A small quantity of fat, the orbital branch of the temporal artery, and a filament from the orbital, or temporo-malar, branch of the superior maxillary nerve, are contained between these two layers. It affords attachment by its inner surface to the superficial fibres of the Temporal muscle.

Dissection.—In order to expose the Temporal muscle, remove the temporal fascia, which may be effected by separating it at its attachment along the upper border of the zygoma, and dissecting it upward from the surface of the muscle. The zygomatic arch should then be divided in front at its junction with the malar bone, and behind near the external auditory meatus, and drawn downward with the Masseter, which should be detached from its insertion into the ramus and angle of the jaw. The whole extent of the Temporal muscle is then exposed.

The Temporal (Fig. 199) is a broad, radiating muscle situated at the side of the head and occupying the entire extent of the temporal fossa. It arises from the whole of the temporal fossa except that portion of it that is formed by the malar bone. Its attachment extends from the external angular process of the frontal in front to the mastoid portion of the temporal behind, and from the curved line on the frontal and parietal bones above to the pterygoid ridge on the great wing of the sphenoid below. It is also attached to the inner surface of the temporal fascia. Its fibres converge as they descend, and terminate in an aponeurosis, the fibres of

FIG. 199.—The Temporal muscle, the zygoma and Masseter having been removed.

which, radiated at its commencement, converge into a thick and flat tendon, which is inserted into the inner surface, apex, and anterior border of the coronoid-process of the jaw, nearly as far forward as the last molar tooth.

Relations.—By its *superficial surface*, with the integument, the Attrahens and Attollens auriculam muscles, the temporal vessels and nerves, the aponeurosis of the Occipito-frontalis, the temporal fascia, the zygoma, and Masseter; by its *deep surface*, with the temporal fossa, the External pterygoid and part of the Buccinator muscles, the internal maxillary artery, its deep temporal branches, and the deep temporal nerves. Behind the tendon are the masseteric vessels and

nerve, and in front of it the buccal vessels and nerve. Its anterior border is separated from the malar bone by a mass of fat.

Nerves.—Both muscles are supplied by the inferior maxillary nerve.

10. Pterygo-mandibular Region (Fig. 200).

External Pterygoid.

Internal Pterygoid.

Dissection.—The Temporal muscle having been examined, saw through the base of the coronoid process, and draw it upward, together with the Temporal muscle, which should be detached from the surface of the temporal fossa. Divide the ramus of the jaw just below the condyle, and also, by a transverse incision extending across the middle, just above the dental foramen; remove the fragment, and the Pterygoid muscles will be exposed.

The **External Pterygoid** is a short, thick muscle, somewhat conical in form, which extends almost horizontally between the zygomatic fossa and the condyle of the jaw. It arises by two heads, separated by a slight interval: the *upper* arises from the inferior surface of the greater wing of the sphenoid and from the pterygoid ridge, which separates the zygomatic from the temporal fossa; the *lower* from the outer surface of the external pterygoid plate. Its fibres pass horizontally backward and outward, to be inserted into a depression in front of the neck of the condyle of the lower jaw and into the corresponding part of the inter-articular fibro-cartilage.

Relations.—By its *external surface*, with the ramus of the lower jaw, the internal maxillary artery, which crosses it,¹ the tendon of the Temporal muscle, and the Masseter; by its *internal surface* it rests against the upper part of the Internal pterygoid, the internal lateral ligament, the middle meningeal artery,

FIG. 200.—The Pterygoid muscles, the zygomatic arch and a portion of the ramus of the jaw having been removed.

and inferior maxillary nerve; by its *upper border* it is in relation with the temporal and masseteric branches of the inferior maxillary nerve; by its *lower border* it is in relation with the inferior dental and gustatory nerves. Through the interval between the two portions of the muscle, the buccal nerve emerges and the internal maxillary artery passes, when the trunk of this vessel lies on the muscle (see Fig. 200).

The **Internal Pterygoid** is a thick, quadrilateral muscle, and resembles the Masseter in form. It arises from the pterygoid fossa, being attached to the inner

¹ This is the usual relation, but in many cases the artery will be found below the muscle.

surface of the external pterygoid plate and to the grooved surface of the tuberosity of the palate bone, and by a second slip from the outer surface of the tuberosities of the palate and superior maxillary bones; its fibres pass downward, outward, and backward, to be inserted, by a strong, tendinous lamina, into the lower and back part of the inner side of the ramus and angle of the lower jaw, as high as the dental foramen.

Relations.—By its *external surface*, with the ramus of the lower jaw, from which it is separated, at its upper part, by the External pterygoid, the internal lateral ligament, the internal maxillary artery, the dental vessels and nerves, and the lingual nerve, and a process of the parotid gland. By its *internal surface*, with the Tensor palati, being separated from the Superior constrictor of the pharynx by a cellular interval.

Nerves.—These muscles are supplied by the inferior maxillary nerve.

Actions.—The Temporal and Masseter and Internal pterygoid raise the lower jaw against the upper with great force. The superficial portion of the Masseter assists the External pterygoid in drawing the lower jaw forward upon the upper, the jaw being drawn back again by the deep fibres of the Masseter and posterior fibres of the Temporal. The External pterygoid muscles are the direct agents in the trituration of the food, drawing the lower jaw directly forward, so as to make the lower teeth project beyond the upper. If the muscle of one side acts, the corresponding side of the jaw is drawn forward, and, the other condyle remaining fixed, the symphysis deviates to the opposite side. The alternation of these movements on the two sides produces trituration.

Surface Form.—The outline of the muscles of the head and face cannot be traced on the surface of the body, except in the case of two of the masticatory muscles. Those of the head are thin, so that the outline of the bone is perceptible beneath them. Those in the face are small, covered by soft skin, and often by a considerable layer of fat, so that their outline is concealed, but they serve to round off and smooth prominent borders and to fill up what would be otherwise unsightly angular depressions. Thus, the Orbicularis palpebrarum rounds off the prominent margin of the orbit, and the Pyramidalis nasi fills in the sharp depression beneath the glabella, and thus softens and tones down the abrupt depression which is seen on the unclothed bone. In like manner, the labial muscles, converging to the lips and assisted by the superimposed fat, fill in the sunken hollow of the lower part of the face. Although the muscles of the face are usually described as arising from the bones and inserted into the nose, lips, and corners of the mouth, they have fibres inserted into the skin of the face along their whole extent, so that almost every point of the skin of the face has its muscular fibre to move it; hence it is that when in action the facial muscles produce alterations in the skin-surface, giving rise to the formation of various folds or wrinkles, or otherwise altering the relative position of parts, so as to produce the varied expressions with which the face is endowed; hence these muscles are termed the “muscles of expression.” The only two muscles in this region which greatly influence surface form are the Masseter and the Temporal. The Masseter is a quadrilateral muscle, which imparts fullness to the hinder part of the cheek. When the muscle is firmly contracted, as when the teeth are clenched, its outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fullness, especially marked at the lower part of the muscle; this fullness is entirely lost when the mouth is opened and the muscle no longer in a state of contraction. The Temporal muscle is fan-shaped, and fills the Temporal fossa, substituting for it a somewhat convex form, the anterior part of which, on account of the absence of hair over the temple, is more marked than the posterior, and stands out in strong relief when the muscle is in a state of contraction.

MUSCLES AND FASCIÆ OF THE NECK.

The muscles of the neck may be arranged into groups corresponding with the region in which they are situated.

These groups are nine in number:

1. Superficial cervical region.
2. Depressors of the Os Hyoides and Larynx.
3. Elevators of the Os Hyoides and Larynx.
4. Muscles of the Tongue.
5. Muscles of the Pharynx.
6. Muscles of the Soft Palate.
7. Muscles of the Anterior Vertebral Region.
8. Muscles of the Lateral Vertebral Region.
9. Muscles of the Larynx.

The muscles contained in each of these groups are the following:

1. *Superficial Region.*

Platysma myoides.
Sterno-cleido-mastoid.

Infra-hyoid Region.

2. *Depressors of the Os hyoides and Larynx.*

Sterno-hyoid.
Sterno-thyroid.
Thyro-hyoid.
Omo-hyoid.

Supra-hyoid Region.

3. *Elevators of the Os hyoides and Larynx.*

Digastric.
Stylo-hyoid.
Mylo-hyoid.
Genio-hyoid.

Lingual Region.

4. *Muscles of the Tongue.*

Genio-hyo-glossus.
Hyo-glossus.
Chondro-glossus.
Stylo-glossus.
Palato-glossus.

5. *Muscles of the Pharynx.*

Inferior constrictor.
Middle constrictor.
Superior constrictor.
Stylo-pharyngeus.
Palato-pharyngeus..

6. *Muscles of the Soft Palate.*

Levator palati.
Tensor palati.
Azygos uvulæ.
Palato-glossus.
Palato-pharyngeus.
Salpingo-pharyngeus.

7. *Muscles of the Anterior Vertebral Region.*

Rectus capitis anticus major.
Rectus capitis anticus minor.
Rectus capitis lateralis.
Longus colli.

8. *Muscles of the Lateral Vertebral Region.*

Scalenus anticus.
Scalenus medius.
Scalenus posticus.

9. *Muscles of the Larynx.*

Included in the description of the Larynx.

1. Superficial Cervical Region.

Platysma myoides.

Sterno-cleido-mastoid.

Dissection.—A block having been placed at the back of the neck, and the face turned to the side opposite that to be dissected, so as to place the parts upon the stretch, make two transverse incisions: one from the chin, along the margin of the lower jaw, to the mastoid process, and the other along the upper border of the clavicle. Connect these by an oblique incision made in the course of the Sterno-mastoid muscle, from the mastoid process to the sternum; the two flaps of integument having been removed in the direction shown in Fig. 194, the superficial fascia will be exposed.

The **Superficial Cervical Fascia** is a thin, aponeurotic lamina which is hardly demonstrable as a separate membrane. Beneath it is found the Platysma myoides muscle.

The **Platysma myoides** (Fig. 195) is a broad, thin plane of muscular fibres placed immediately beneath the superficial fascia on each side of the neck. It arises by thin, fibrous bands from the fascia covering the upper part of the Pectoral and Deltoid muscles; its fibres pass over the clavicle and proceed obliquely upward and inward along the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres pass over the lower jaw, some of them being attached to the bone below the external oblique line, others passing on to be inserted into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomatic muscles or to the margin of the Orbicularis oris. Beneath the Platysma the external jugular vein may be seen descending from the angle of the jaw to the clavicle.

Surgical Anatomy.—It is essential to remember the direction of the fibres of the *Platysma* in connection with the operation of bleeding from the external jugular vein; for if the point of the lancet is introduced in the direction of the muscular fibres, the orifice made will be filled up by the contraction of the muscle, and blood will not flow; but if the incision is made across the course of the fibres, they will retract and expose the orifice in the vein, and so allow the flow of blood.

Relations.—By its *external surface*, with the integument, to which it is united more closely below than above; by its *internal surface*, with the *Pectoralis major* and *Deltoid*, and with the *clavicle*. In the *neck*, with the external and anterior jugular veins, the deep cervical fascia, the superficial branches of the cervical plexus, the *Sterno-mastoid*, *Sterno-hyoid*, *Omo-hyoid*, and *Digastric* muscles; behind the *Sterno-mastoid* muscle it covers in the posterior triangle of the neck. On the *face* it is in relation with the *parotid gland*, the *facial artery* and vein, and the *Masseter* and *Buccinator* muscles.

Action.—The *Platysma myoides* produces a slight wrinkling of the surface of the skin of the neck, in an oblique direction, when the entire muscle is brought into action. Its anterior portion, the thickest part of the muscle, depresses the lower jaw; it also serves to draw down the lower lip and angle of the mouth on each side, being one of the chief agents in the expression of melancholy.

The **Deep cervical fascia** lies under cover of the *Platysma myoides* muscle and constitutes a complete investment for the neck. It also forms a sheath for the carotid vessels, and, in addition, is prolonged deeply in the shape of certain processes or lamellæ, which come into close relation with the structures situated in front of the vertebral column.

The investing portion of the fascia is attached behind to the *ligamentum nuchæ* and to the spine of the seventh cervical vertebra. Along this line it splits to enclose the *Trapezius* muscle, at the anterior border of which the two enclosing lamellæ unite and form a strong membrane, which extends forward so as to roof in the posterior triangle of the neck. Along the hinder edge of the *Sterno-mastoid* this membrane again divides to enclose this muscle, at the anterior edge of which it once more forms a single lamella, which roofs in the anterior triangle of the neck, and, reaching forward to the middle line, is continuous with the corresponding part from the opposite side of the neck. In the middle line of the neck it is attached to the *symphysis menti* and body of the *hyoid bone*.

Above, the fascia is attached to the superior curved line of the occiput, to the mastoid process of the temporal, and to the whole length of the body of the jaw. Opposite the angle of the jaw the fascia is very strong, and binds the anterior edge of the *Sterno-mastoid* firmly to that bone. Between the jaw and the mastoid process it ensheaths the *parotid gland*—the layer which covers the gland extending upward under the name of the *parotid fascia* to be fixed to the *zygomatic arch*. From the layer which passes under the *parotid* a strong band, the *stylo-mandibular ligament*, reaches from the *styloid process* to the angle of the jaw.

Below, the fascia is attached to the *acromion process*, the *clavicle*, and *manubrium sterni*. Some little distance above the last, however, it splits into two layers, superficial and deep. The former is attached to the anterior border of the *manubrium*, the latter to its posterior border and to the *interclavicular ligament*. Between these two layers is a slit-like interval, the *suprasternal space*, or *space of Burns*. It contains a small quantity of areolar tissue, and sometimes a lymphatic gland; the lower portions of the anterior jugular veins and their transverse connecting branch; and also the sternal heads of the *Sterno-mastoid* muscles.

The fascia which lines the deep aspect of the *Sterno-mastoid* gives off certain important processes, viz.: (1) A process to envelop the tendon of the *Omo-hyoid*, and bind it down to the sternum and first costal cartilage. (2) A strong sheath, the *carotid sheath*, for the large vessels of the neck, enclosed within which are the *carotid artery*, *internal jugular vein*, the *vagus*, and *descendens hypoglossi* nerves. (3) The *prevertebral fascia*, which extends inward behind the carotid vessels, where it assists in forming their sheath, and passes in front of the *prevertebral* muscles. It thus forms the posterior limit of a fibrous compartment which contains

the larynx and trachea, the thyroid gland, and the pharynx and œsophagus. The prevertebral fascia is fixed above to the base of the skull, while below it is continued into the thorax in front of the Longus colli muscles. Parallel to the carotid vessels and along their inner aspect it gives off a thin lamina, the *bucco-pharyngeal fascia*, which closely invests the constrictor muscles of the pharynx, and is continued forward from the Superior constrictor on to the Buccinator. It is attached to the prevertebral layer by loose connective tissue only, and thus an easily distended space, the *retro-pharyngeal space*, is found between them. This space is limited above by the base of the skull, while below it extends behind the

FIG. 201.—Section of the neck at about the level of the sixth cervical vertebra. Showing the arrangement of the deep cervical fascia.

œsophagus into the thorax, where it is continued into the posterior mediastinum. The prevertebral fascia is prolonged downward and outward behind the carotid vessels and in front of the Scaleni muscles, and forms a sheath for the brachial nerves and subclavian vessels in the posterior triangle of the neck, and, continued under the clavicle as the axillary sheath, is attached to the deep surface of the costo-coracoid membrane. Immediately above the clavicle an areolar space exists between the investing layer and the sheath of the subclavian vessels, and in it are found the lower part of the external jugular vein, the descending claviclar nerves, the suprascapular and transversalis colli vessels, and the posterior belly of the

Omo-hyoid muscle. This space extends downward behind the clavicle, and is limited below by the fusion of the costo-coracoid membrane with the anterior wall of the axillary sheath. (4) The pre-tracheal fascia, which extends inward in front of the carotid vessels, and assists in forming the carotid sheath. It is further continued behind the depressor muscles of the hyoid bone, and, after enveloping the thyroid body, is prolonged in front of the trachea to meet the corresponding layer of the opposite side. Above, it is fixed to the hyoid bone, while below it is carried downward in front of the trachea and large vessels at the root of the neck, and ultimately blends with the fibrous pericardium.

Surgical Anatomy.—The cervical fascia is of considerable importance from a surgical point of view. As will be seen from the foregoing description, it may be divided into three layers: (1) A superficial layer; (2) a layer passing in front of the trachea, and forming with the superficial layer a sheath for the depressors of the hyoid bone; (3) a prevertebral layer passing in front of the bodies of the cervical vertebræ, and forming with the second layer a space in which are contained the trachea, œsophagus, etc. The superficial layer forms a complete investment for the neck. It is attached behind to the ligamentum nuchæ and the spine of the seventh cervical vertebra; above it is attached to the external occipital protuberance, to the superior curved line of the occiput, to the mastoid process, to the zygoma and the lower jaw; below it is attached to the manubrium sterni, the clavicle, the acromion process, and the spine of the scapula; in front it blends with the fascia of the opposite side. This layer would oppose the extension of abscesses or new growths toward the surface, and pus forming beneath it would have a tendency to extend laterally. If it is in the posterior triangle, it might extend backward under the Trapezius, forward under the Sterno-mastoid, or downward under the clavicle for some distance, until stopped by the junction of the cervical fascia to the Costo-coracoid membrane. If the pus is contained in the anterior triangle, it might find its way into the anterior mediastinum, being situated in front of the layer of fascia which passes down into the thorax to become continuous with the pericardium; but owing to the lesser density and thickness of the fascia in this situation it more frequently finds its way through it and points above the sternum. The second layer of fascia is connected above with the hyoid bone. It passes down beneath the depressors and in front of the thyroid body and trachea to become continuous with the fibrous layer of the pericardium. Laterally it invests the great vessels of the neck and is connected with the superficial layer beneath the Sterno-mastoid. Pus forming beneath this layer would in all probability find its way into the posterior mediastinum. The third layer (the prevertebral fascia) is connected above to the base of the skull. Pus forming beneath this layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, might extend toward the posterior and lateral part of the neck and point in this situation, or might perforate this layer of fascia and the pharyngeal fascia and point into the pharynx (retro-pharyngeal abscess).

In cases of cut throat the cervical fascia is of considerable importance. When the wound involves only the superficial layer the injury is usually trivial, the only special danger being injury to the external jugular vein, and the only special complication being diffuse cellulitis. But where the second of the two layers has been opened up, important structures may have been injured, which may lead to serious results.

It may be worth while mentioning that in Burns's space is contained the sternal head of origin of the Sterno-mastoid muscle, so that this space is opened in division of this tendon. The anterior jugular vein is also contained in the same space.

The **Sterno-mastoid** or **Sterno-cleido-mastoid** (Fig. 202) is a large, thick muscle, which passes obliquely across the side of the neck, being enclosed between the two layers of the deep cervical fascia. It is thick and narrow at its central part, but is broader and thinner at each extremity. It arises, by two heads, from the sternum and clavicle. The *sternal portion* is a rounded fasciculus, tendinous in front, fleshy behind, which arises from the upper and anterior part of the first piece of the sternum, and is directed upward, outward, and backward. The *clavicular portion* arises from the inner third of the superior border and anterior surface of the clavicle, being composed of fleshy and aponeurotic fibres; it is directed almost vertically upward. These two portions are separated from one another, at their origin, by a triangular cellular interval, but become gradually blended, below the middle of the neck, into a thick, rounded muscle, which is inserted, by a strong tendon, into the outer surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the outer half of the superior curved line of the occipital bone. The Sterno-mastoid varies much in its extent of attachment to the clavicle: in one case the clavicular may be as narrow as the sternal portion; in another, as much as three inches in breadth. When the clavicular

origin is broad, it is occasionally subdivided into numerous slips separated by narrow intervals. More rarely, the corresponding margins of the Sterno-mastoid and Trapezius have been found in contact. In the application of a ligature to the third part of the subclavian artery it will be necessary, where the muscles come close together, to divide a portion of one or of both.

This muscle divides the quadrilateral space at the side of the neck into two triangles, an anterior and a posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck; above, the lower border of the body of the jaw, and an imaginary line drawn from the angle of the jaw to the mastoid

FIG. 202.—Muscles of the neck and boundaries of the triangles.

process; behind, the anterior border of the Sterno-mastoid muscle. The apex of the triangle is at the upper border of the sternum. The boundaries of the *posterior triangle* are, in front, the posterior border of the Sterno-mastoid; below, the middle third of the clavicle; behind, the anterior margin of the Trapezius.¹ The apex corresponds with the meeting of the Sterno-mastoid and Trapezius on the occipital bone.

Relations.—By its *superficial surface*, with the integument and Platysma, from which it is separated by the external jugular vein, the superficial branches of the cervical plexus, and the anterior layer of the deep cervical fascia. By its *deep surface* it is in relation with the Sterno-clavicular articulation; a process of the deep cervical fascia; the Sterno-hyoid, Sterno-thyroid, Omo-hyoid, posterior belly of the Digastric, Levator anguli scapulæ, Splenius and Scalenii muscles; common carotid artery, internal and anterior jugular veins, commencement of the internal and external carotid arteries, the occipital, subclavian, transversalis colli, and suprascapular arteries and veins; the phrenic, pneumogastric, hypoglossal, descendens and communicans hypoglossi nerves; the spinal accessory nerve, which

¹ The anatomy of these triangles will be more exactly described with that of the vessels of the neck.

pierces its upper third; the cervical plexus, parts of the thyroid and parotid glands, and deep lymphatic glands.

Nerves.—The *Platysma myoides* is supplied by the facial nerve; the *Sterno-cleido-mastoid*, by the spinal accessory and deep branches of the cervical plexus.

Actions.—When only one *Sterno-mastoid* muscle acts, it draws the head toward the shoulder of the same side, assisted by the *Splenius* and the *Obliquus capitis inferior* of the opposite side. At the same time it rotates the head so as to carry the face toward the opposite side. If the head is fixed, the two muscles assist in elevating the thorax in forced inspiration.

Surface Form.—The anterior edge of the muscle forms a very prominent ridge beneath the skin, which it is important to notice, as it forms a guide to the surgeon in making the necessary incisions for ligature of the common carotid artery and for oesophagotomy.

Surgical Anatomy.—The relations of the sternal and clavicular parts of the *Sterno-mastoid* should be carefully examined, as the surgeon is sometimes required to divide one or both portions of the muscles in *wry-neck*. One variety of this distortion is produced by spasmodic contraction or rigidity of the *Sterno-mastoid*; the head being carried down toward the shoulder of the same side, and the face turned to the opposite side and fixed in that position. When there is permanent shortening, subcutaneous division of the muscle is resorted to by some surgeons. This is performed by introducing a tenotomy knife beneath it, close to its origin, and dividing it from behind forward whilst the muscle is put well upon the stretch. There is seldom any difficulty in dividing the sternal portion by making a puncture on the inner side of the tendon, and then pushing a blunt tenotome behind it, and cutting forward. In dividing the clavicular portion care must be taken to avoid wounding the external jugular vein, which runs parallel with the posterior border of the muscle in this situation, or the anterior jugular vein, which crosses beneath it. If the external jugular vein lies near the muscle, it is safer to make the first puncture at the outer side of the tendon, and introduce a blunt tenotome from without inward. Many surgeons prefer dividing the muscle by the open method. An incision is made over either origin of the muscle, the tendon is exposed, a director is passed underneath it, and it is then divided. With care and attention to asepsis this plan of treatment is devoid of risk, and in this way the accidental division of the vessels can be avoided. Some of the fibres of the *Sterno-mastoid* muscle are occasionally torn during birth, especially in breech presentations; this is accompanied by hemorrhage and formation of a swelling within the substance of the muscle. This by some is believed to be one of the causes of *wry-neck*, the scar tissue which is formed contracting and shortening the muscle.

2. Infra-hyoid Region (Figs. 202, 203).

DEPRESSORS OF THE OS HYOIDES AND LARYNX.

Sterno-hyoid.

Thyro-hyoid.

Sterno-thyroid.

Omo-hyoid.

Dissection.—The muscles in this region may be exposed by removing the deep fascia from the front of the neck. In order to see the entire extent of the *Omo-hyoid* it is necessary to divide the *Sterno-mastoid* at its centre, and turn its ends aside, and to detach the *Trapezius* from the clavicle and scapula. This, however, should not be done until the *Trapezius* has been dissected.

The *Sterno-hyoid* is a thin, narrow, ribbon-like muscle, which arises from the inner extremity of the clavicle, the posterior sterno-clavicular ligament, and the upper and posterior part of the first piece of the sternum; passing upward and inward, it is inserted, by short, tendinous fibres, into the lower border of the body of the *os hyoides*. This muscle is separated, below, from its fellow by a considerable interval; but the two muscles come into contact with one another in the middle of their course, and from this upward lie side by side. It sometimes presents, immediately above its origin, a transverse tendinous intersection, like those in the *Rectus abdominis*.

Relations.—By its *superficial surface*, below, with the sternum, the sternal end of the clavicle, and the *Sterno-mastoid*; and above, with the *Platysma* and deep cervical fascia; by its *deep surface*, with the *Sterno-thyroid*, *Crico-thyroid*, and *Thyro-hyoid* muscles, the thyroid gland, the superior thyroid vessels, the thyroid cartilage, the *crico-thyroid* and *thyro-hyoid* membranes.

The *Sterno-thyroid* is situated beneath the preceding muscle, but is shorter and wider than it. It arises from the posterior surface of the first bone of the sternum,

below the origin of the Sterno-hyoid, and from the edge of the cartilage of the first rib, occasionally of the second rib also, and is inserted into the oblique line on the side of the ala of the thyroid cartilage. This muscle is in close contact with its fellow at the lower part of the neck, and is occasionally traversed by a transverse or oblique tendinous intersection, like those in the Rectus abdominis.

Relations.—By its *anterior surface*, with the Sterno-hyoid, Omo-hyoid, and Sterno-mastoid; by its *posterior surface*, from below upward, with the trachea, vena innominata, common carotid (and on the right side the arteria innominata), the thyroid gland and its vessels, and the lower part of the larynx and pharynx. The inferior thyroid vein lies along its inner border, a relation which it is important to remember in the operation of tracheotomy. On the left side the deep surface of the muscle is in relation to the œsophagus.

The **Thyro-hyoid** is a small, quadrilateral muscle appearing like a continuation of the Sterno-thyroid. It arises from the oblique line on the side of the thyroid cartilage, and passes vertically upward to be inserted into the lower border of the body and greater cornu of the hyoid bone.

Relations.—By its *external surface*, with the Sterno-hyoid and Omo-hyoid muscles; by its *internal surface*, with the thyroid cartilage, the thyro-hyoid membrane, and the superior laryngeal vessels and nerve.

The **Omo-hyoid** passes across the side of the neck, from the scapula to the

FIG. 203.—Muscles of the neck. Anterior view.

hyoid bone. It consists of two fleshy bellies, united by a central tendon. It arises from the upper border of the scapula, and occasionally from the transverse ligament which crosses the suprascapular notch, its extent of attachment to the scapula varying from a few lines to an inch. From this origin the posterior belly forms a flat, narrow fasciculus, which inclines forward and slightly upward across the lower part of the neck, behind the Sterno-mastoid muscle, where it becomes tendinous; it then changes its direction, forming an obtuse angle, and terminates in the anterior belly, which passes almost vertically upward, close to the outer border of the Sterno-hyoid, to be inserted into the lower border of the body of the

os hyoides, just external to the insertion of the Sterno-hyoid. The central tendon of this muscle, which varies much in length and form, is held in position by a process of the deep cervical fascia, which includes it in a sheath. This process is prolonged down, to be attached to the clavicle and first rib. It is by this means that the angular form of the muscle is maintained.

This muscle subdivides each of the two large triangles at the side of the neck into two smaller triangles; the two posterior ones being the *posterior superior* or *occipital*, and the *posterior inferior* or *subclavian*; the two anterior, the *anterior superior* or *superior carotid*, and the *anterior inferior* or *inferior carotid triangles*.

Relations.—By its *superficial surface*, with the Trapezius, the Sterno-mastoid, deep cervical fascia, Platysma, and integument; by its *deep surface*, with the Scaleni muscles, phrenic nerve, lower cervical nerves, which go to form the brachial plexus, the suprascapular vessels and nerve, sheath of the common carotid artery and internal jugular vein, the Sterno-thyroid and Thyro-hyoid muscles.

Nerves.—The Thyro-hyoid is supplied by the hypoglossal; the other muscles of this group by branches from the loop of communication between the descendens and communicans hypoglossi.

Actions.—These muscles depress the larynx and hyoid bone, after they have been drawn up with the pharynx in the act of deglutition. The Omo-hyoid muscles not only depress the hyoid bone, but carry it backward and to one or the other side. It is concerned especially in prolonged inspiratory efforts; for by tensing the lower part of the cervical fascia it lessens the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. The Thyro-hyoid may act as an elevator of the thyroid cartilage when the hyoid bone ascends, drawing upward the thyroid cartilage, behind the os hyoides. The Sterno-thyroid acts as a depressor of the thyroid cartilage.

3. Supra-hyoid Region (Figs. 202, 203).

ELEVATORS OF THE OS HYOIDES—DEPRESSORS OF THE LOWER JAW.

Digastric.

Mylo-hyoid.

Stylo-hyoid.

Genio-hyoid.

Dissection.—To dissect these muscles a block should be placed beneath the back of the neck, and the head drawn backward and retained in that position. On the removal of the deep fascia the muscles are at once exposed.

The **Digastric** consists of two fleshy bellies united by an intermediate, rounded tendon. It is a small muscle, situated below the side of the body of the lower jaw, and extending, in a curved form, from the side of the head to the symphysis of the jaw. The *posterior belly*, longer than the anterior, arises from the digastric groove on the inner side of the mastoid process of the temporal bone, and passes downward, forward, and inward. The *anterior belly* arises from a depression on the inner side of the lower border of the jaw, close to the symphysis, and passes downward and backward. The two bellies terminate in the central tendon which perforates the Stylo-hyoid, and is held in connection with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, lined by a synovial membrane. A broad aponeurotic layer is given off from the tendon of the Digastric on each side, which is attached to the body and great cornu of the hyoid bone: this is termed the *supra-hyoid aponeurosis*. It forms a strong layer of fascia between the anterior portion of the two muscles, and a firm investment for the other muscles of the supra-hyoid region which lie deeper.

The Digastric muscle divides the anterior superior triangle of the neck into two smaller triangles; the upper, or *submaxillary*, being bounded, above, by the lower border of the body of the jaw, and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and the Stylo-hyoid muscles; in front, by the middle line of the neck and the anterior belly of the Digastric, the lower or *superior carotid triangle* being bounded above by the posterior belly of the Digastric, behind by the Sterno-mastoid, below by the Omo-hyoid.

Relations.—By its *superficial surface* with the mastoid process, the Platysma, Sterno-mastoid, part of the Splenius, Trachelo-mastoid, and Stylo-hyoid muscles, and the parotid gland. By its *deep surface*, the anterior belly lies on the Mylo-hyoid; the posterior belly on the Stylo-glossus, Stylo-pharyngeus, and Hyo-glossus muscles, the external carotid artery and its occipital, lingual, facial, and ascending pharyngeal branches, the internal carotid artery, internal jugular vein, and hypoglossal nerve.

The **Stylo-hyoid** is a small, slender muscle, lying in front of, and above, the posterior belly of the Digastric. It arises from the back and outer surface of the styloid process, near the base; and, passing downward and forward, is inserted into the body of the hyoid bone, just at its junction with the greater cornu, and immediately above the Omo-hyoid. This muscle is perforated, near its insertion, by the tendon of the Digastric.

Relations.—By its *superficial surface* above with the parotid gland and deep cervical fascia; below it is superficial, being situated immediately beneath the deep cervical fascia. By its *deep surface*, with the posterior belly of the Digastric, the external carotid artery, with its lingual and facial branches, the Hyo-glossus muscle, and the hypoglossal nerve.

The Stylo-hyoid Ligament.—In connection with the Stylo-hyoid muscle may be described a ligamentous band, the *Stylo-hyoid ligament*. It is a fibrous cord, often containing a little cartilage in its centre, which continues the styloid process down to the hyoid bone, being attached to the tip of the former and the small cornu of the latter. It is often more or less ossified, and in many animals forms a distinct bone, the *epihyal*.

The anterior belly of the Digastric should be removed, in order to expose the next muscle.

The **Mylo-hyoid** is a flat, triangular muscle, situated immediately beneath the anterior belly of the Digastric, and forming, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It arises from the whole length of the mylo-hyoid ridge of the lower jaw, extending from the symphysis in front to the last molar tooth behind. The posterior fibres pass inward and slightly downward, to be inserted into the body of the os hyoides. The middle and anterior fibres are inserted into a median fibrous raphé, extending from the symphysis of the lower jaw to the hyoid bone, where they join at an angle with the fibres of the opposite muscle. The median raphé is sometimes wanting; the muscular fibres of the two sides are then directly continuous with one another.

Relations.—By its *cutaneous or under surface*, with the Platysma, the anterior belly of the Digastric, the supra-hyoid aponeurosis, the submaxillary gland, submental vessels, and mylo-hyoid vessels and nerve; by its *deep or superior surface*, with the Genio-hyoid, part of the Hyo-glossus and Stylo-glossus muscles, the hypoglossal and lingual nerves, the submaxillary ganglion, the sublingual gland, the deep portion of the submaxillary gland, and Wharton's duct; the sublingual and ranine vessels, and the buccal mucous membrane.

Dissection.—The Mylo-hyoid should now be removed, in order to expose the muscles which lie beneath; this is effected by reflecting it from its attachments to the hyoid bone and jaw, and separating it by a vertical incision from its fellow of the opposite side.

The **Genio-hyoid** is a narrow, slender muscle, situated immediately beneath¹ the inner border of the preceding. It arises from the inferior genial tubercle on the inner side of the symphysis of the jaw, and passes downward and backward, to be inserted into the anterior surface of the body of the os hyoides. This muscle lies in close contact with its fellow of the opposite side, and increases slightly in breadth as it descends.

Relations.—It is covered by the Mylo-hyoid, and lies along the lower border of the Genio-hyo-glossus.

Nerves.—The Digastric is supplied: its anterior belly, by the mylo-hyoid branch

¹ This refers to the depth of the muscles from the skin in the order of dissection. In the erect position of the body each of these muscles lies above the preceding.

of the inferior dental; its posterior belly, by the facial; the Stylo-hyoid, by the facial; the Mylo-hyoid, by the mylo-hyoid branch of the inferior dental; the Genio-hyoid, by the hypoglossal.

Actions.—This group of muscles performs two very important actions. They raise the hyoid bone, and with it the base of the tongue, during the act of deglutition; or, when the hyoid bone is fixed by its depressors and those of the larynx, they depress the lower jaw. During the first act of deglutition, when the mass is being driven from the mouth into the pharynx, the hyoid bone, and with it the tongue, is carried upward and forward by the anterior belly of the Digastric, the Mylo-hyoid, and Genio-hyoid muscles. In the second act, when the mass is passing through the pharynx, the direct elevation of the hyoid bone takes place by the combined action of all the muscles; and after the food has passed the hyoid bone is carried upward and backward by the posterior belly of the Digastric and Stylo-hyoid muscles, which assist in preventing the return of the morsel into the mouth.

4. Lingual Region.

Genio-hyo-glossus.

Stylo-glossus.

Hyo-glossus.

Palato-glossus.

Chondro-glossus.

Dissection.—After completing the dissection of the preceding muscles, saw through the lower jaw just external to the symphysis. Then draw the tongue forward, and attach it, by a stitch, to the nose; when its muscles, which are thus put on the stretch, may be examined.

The **Genio-hyo-glossus** has received its name from its triple attachment to the jaw, hyoid bone, and tongue, but it would be better named the *Genio-glossus*,

FIG. 204.—Muscles of the tongue. Left side.

since its attachment to the hyoid bone is very slight or altogether absent. It is a flat, triangular muscle, placed vertically on either side of the middle line, its apex

corresponding with its point of attachment to the lower jaw, its base with its insertion into the tongue and hyoid bone. It arises by a short tendon from the superior genial tubercle on the inner side of the symphysis of the jaw, immediately above the Genio-hyoid; from this point the muscle spreads out in a fan-like form, a few of the inferior fibres passing downward, to be attached by a thin aponeurosis into the upper part of the body of the hyoid bone, a few fibres passing between the Hyo-glossus and Chondro-glossus to blend with the Constrictor muscles of the pharynx; the middle fibres passing backward, and the superior ones upward and forward, to enter the whole length of the under surface of the tongue, from the base to the apex. The two muscles lie on either side of the median plane; behind, they are quite distinct from each other, and are separated at their insertion into the under surface of the tongue by a tendinous raphé, which extends through the middle of the organ; in front, the two muscles are more or less blended: distinct fasciculi are to be seen passing off from one muscle, crossing the middle line, and intersecting with bundles of fibres derived from the muscle on the other side (Fig. 205).

Relations.—By its *internal surface* it is in contact with its fellow of the opposite side; by its *external surface*, with the Inferior lingualis, the Hyo-glossus, the lingual artery and hypoglossal nerve, the lingual nerve, and sublingual gland; by its *upper border*, with the mucous membrane of the floor of the mouth (frænum linguæ); by its *lower border*, with the Genio-hyoid.

The **Hyo-glossus** is a thin, flat, quadrilateral muscle which arises from the side of the body and whole length of the greater cornu of the hyoid bone, and passes almost vertically upward to enter the side of the tongue, between the Stylo-glossus and Lingualis. Those fibres of this muscle which arise from the body are directed upward and backward, overlapping those arising from the greater cornu, which are directed upward and forward.

Relations.—By its *external surface*, with the Digastric, the Stylo-hyoid, Stylo-glossus, and Mylo-hyoid muscles, the submaxillary ganglion, the lingual and hypoglossal nerves, Wharton's duct, the ranine vein, the sublingual gland, and the deep portion of the submaxillary gland. By its *deep surface*, with the Stylo-hyoid ligament, the Genio-hyo-glossus, Lingualis, and Middle constrictor, the lingual vessels, and the glosso-pharyngeal nerve.

The **Chondro-glossus** is a distinct muscular slip, though it is sometimes described as a part of the Hyo-glossus, from which, however, it is separated by the fibres of the Genio-hyo-glossus, which pass to the side of the pharynx. It is about three-quarters to an inch in length, and arises from the inner side and base of the lesser cornu and contiguous portion of the body of the

CHONDRO-GLOSSUS.

FIG. 205.—Muscles of the tongue from below. (From a preparation in the Museum of the Royal College of Surgeons of England.)

hyoid bone, and passes directly upward to blend with the intrinsic muscular fibres of the tongue, between the Hyo-glossus and Genio-hyo-glossus. A small slip of muscular fibre is occasionally found, arising from the cartilago triticea in the thyro-hyoid ligament, and passing upward and forward to enter the tongue with the hindmost fibres of the Hyo-glossus.

The **Stylo-glossus**, the shortest and smallest of the three styloid muscles, arises from the anterior and outer side of the styloid process, near its apex, and from the

stylo-mandibular ligament, to which its fibres, in most cases, are attached by a thin aponeurosis. Passing downward and forward between the internal and external carotid arteries, and becoming nearly horizontal in its direction, it divides upon the side of the tongue into two portions: one longitudinal, which enters the side of the tongue near its dorsal surface, blending with the fibres of the Lingualis in front of the Hyo-glossus; the other oblique, which overlaps the Hyo-glossus muscle and decussates with its fibres.

Relations.—By its *external surface*, from above downward, with the parotid gland, the Internal pterygoid muscle, the lingual nerve, and the mucous membrane of the mouth; by its *internal surface*, with the tonsil, the Superior constrictor, and the Hyo-glossus muscle.

The Palato-glossus, or Constrictor isthmi faucium, although it is one of the muscles of the tongue, serving to draw its base upward during the act of deglutition, is more nearly associated with the soft palate, both in its situation and function; it will consequently be described with that group of muscles.

Nerves.—The Palato-glossus is probably innervated by the spinal accessory nerve, through the pharyngeal plexus; the remaining muscles of this group, by the hypoglossal.

Muscular Substance of Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets—Extrinsic and Intrinsic. The extrinsic muscles of the tongue are those which have their origin external, and only their terminal fibres contained in the substance of the organ. They are: the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngeo-glossus). The intrinsic are those which are contained entirely within the tongue, and form the greater part of its muscular structure.

The tongue consists of symmetrical halves separated from each other in the middle line by a fibrous septum. Each half is composed of muscular fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves.

CUT EDGE OF SUPERIOR LINGUALIS.

FIG. 206.—Muscles on the dorsum of the tongue.

FIG. 207.—Coronal section of tongue. Showing intrinsic muscles. (Altered from Krause.) a, lingual artery; b, inferior lingualis, cut through; c, fibres of Hyo-glossus; d, oblique fibres of Stylo-glossus; e, insertion of Transverse lingualis; f, Superior lingualis; g, papillae to tongue; h, vertical fibres of Genio-hyo-glossus intersecting Transverse lingualis; i, septum.

To demonstrate the various fibres of the tongue, the organ should be subjected to prolonged boiling, in order to soften the connective tissue; the dis-

section may then be commenced from the dorsum (Fig. 206). Immediately beneath the mucous membrane is a submucous, fibrous layer, into which the muscular fibres which terminate on the surface of the tongue are inserted. Upon removing this, with the mucous membrane, the first stratum of muscular fibres is exposed. This belongs to the group of intrinsic muscles, and has been named the *Superior lingualis* (*m. longitudinalis superior*). It consists of a thin layer of oblique and longitudinal fibres which arise from the submucous fibrous layer, close to the Epiglottis, and from the fibrous septum, and pass forward and outward to the edges of the tongue. Between its fibres pass some vertical fibres derived from the Genio-hyo-glossus and from the vertical intrinsic muscle, which will be described later on. Beneath this layer is the second stratum of muscular fibres, derived principally from the extrinsic muscles. In front it is formed by the fibres derived from the Stylo-glossus, running along the side of the tongue, and sending one set of fibres over the dorsum which runs obliquely forward and inward to the middle line, and another set of fibres, seen at a later period of the dissection, on to the under surface of the sides of the anterior part of the tongue, which run forward and inward, between the fibres of the Hyo-glossus, to the middle line. Behind this layer of fibres, derived from the Stylo-glossus, are fibres derived from the Hyo-glossus, assisted by some few fibres of the Palato-glossus. The Hyo-glossus, entering the side of the under surface of the tongue, between the Stylo-glossus and Inferior lingualis, passes round its margin and spreads out into a layer on the dorsum, which occupies the middle third of the organ, and runs almost transversely inward to the septum. It is reinforced by some fibres from the Palato-glossus; other fibres of this muscle pass more deeply and intermingle with the next layer. The posterior part of the second layer of the muscular fibres of the tongue is derived from those fibres of the Hyo-glossus which arise from the lesser cornu of the hyoid bone, and are here described as a separate muscle—the Chondro-glossus. The fibres of this muscle are arranged in a fan-shaped manner, and spread out over the posterior third of the tongue. Beneath this layer is the great mass of the intrinsic muscles of the tongue, intersected at right angles by the terminal fibres of one of the extrinsic muscles—the Genio-hyo-glossus. This portion of the tongue is paler in color and softer in texture than that already described, and is sometimes designated the medullary portion in contradistinction to the firmer superficial part, which is termed the cortical portion. It consists largely of transverse fibres, the *Transverse lingualis* (*m. transversus linguae*), and of vertical fibres, the *Vertical lingualis* (*m. verticulis linguae*). The Transverse lingualis forms the largest portion of the third layer of muscular fibres of the tongue. The fibres arise from the median septum, and pass outward to be inserted into the submucous fibrous layer at the sides of the tongue. Intermingled with these transverse intrinsic fibres are transverse extrinsic fibres derived from the Palato-glossus and the Superior constrictor of the pharynx. These transverse extrinsic fibres, however, run in the opposite direction, passing inward toward the septum. Intersecting the transverse fibres are a large number of vertical fibres derived partly from the Genio-hyo-glossus and partly from intrinsic fibres, the Vertical lingualis. The fibres derived from the Genio-hyo-glossus enter the under surface of the tongue on each side of the median septum from base to apex. They ascend in a radiating manner to the dorsum, being inserted into the submucous fibrous layer covering the tongue on each side of the middle line. The Vertical lingualis is found only at the borders of the fore part of the tongue, external to the fibres of the Genio-hyo-glossus. Its fibres extend from the upper to the under surface of the organ, decussating with the fibres of the other muscles, and especially with the Transverse lingualis. The fourth layer of muscular fibres of the tongue consists partly of extrinsic fibres derived from the Stylo-glossus, and partly of intrinsic fibres, the *Inferior lingualis* (*m. longitudinalis inferior*). At the sides of the under surface of the organ are some fibres derived from the Stylo-glossus, which, as it runs forward at the side of the tongue, gives off fibres which, passing forward and inward between the fibres of the Hyo-glossus, form an inferior oblique stratum which joins in front with the

anterior fibres of the Inferior lingualis. The Inferior lingualis is a longitudinal band, situated on the under surface of the tongue, and extending from the base to the apex of the organ. Behind, some of its fibres are connected with the body of the hyoid bone. It lies between the Hyo-glossus and the Genio-hyo-glossus, and in front of the Hyo-glossus it gets into relation with the Stylo-glossus, with the fibres of which it blends. It is in relation by its under surface with the ranine artery.

Surgical Anatomy.—The fibrous septum which exists between the two halves of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free, a fact often illustrated by injecting one-half of the tongue with colored size, while the other half is left uninjected or is injected with size of a different color.

This is a point of considerable importance in connection with removal of one-half of the tongue for cancer, an operation which is now frequently resorted to when the disease is strictly confined to one side of the tongue. If the mucous membrane is divided longitudinally exactly in the middle line, the tongue can be split into halves along the median raphe without any appreciable hæmorrhage, and the diseased half can then be removed.

Actions.—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The *Genio-hyo-glossi* muscles, by means of their posterior fibres, draw the base of the tongue forward, so as to protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The whole length of these two muscles, acting along the middle line of the tongue, draw it downward, so as to make it concave from side to side, forming a channel along which fluids may pass toward the pharynx, as in sucking. The *Hyo-glossi* muscles depress the tongue and draw down its sides, so as to render it convex from side to side. The *Stylo-glossi* muscles draw the tongue upward and backward. The *Palato-glossi* muscles draw the base of the tongue upward. With regard to the intrinsic muscles, both the Superior and Inferior linguales tend to shorten the tongue, but the former, in addition, turn the tip and sides upward so as to render the dorsum concave, while the latter pull the tip downward and cause the dorsum to become convex. The Transverse lingualis narrows and elongates the tongue, and the Vertical lingualis flattens and broadens it. The complex arrangement of the muscular fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the various forms necessary for the enunciation of the different consonantal sounds; and Dr. Macalister states that "there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages."

5. Pharyngeal Region.

Inferior constrictor.	Superior constrictor.
Middle constrictor.	Stylo-pharyngeus.
Palato-pharyngeus.	} (See next section.)
Salpingo-pharyngeus.	

Dissection (Fig. 208).—In order to examine the muscles of the pharynx, cut through the trachea and œsophagus just above the sternum, and draw them upward by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forward, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upward. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The Inferior constrictor, the most superficial and thickest of the three constrictors, arises from the sides of the cricoid and thyroid cartilages. To the cricoid cartilage it is attached in the interval between the Crico-thyroid muscle in front and the articular facet for the thyroid cartilage behind. To the thyroid cartilage it is attached to the oblique line on the side of the great ala, the cartilaginous surface behind it, nearly as far as its posterior border, and to the inferior cornu. From these attachments the fibres spread backward and inward, to be inserted into the fibrous raphe in the posterior median line of the pharynx.

The inferior fibres are horizontal, and continuous with the fibres of the œsophagus: the rest ascend, increasing in obliquity, and overlap the Middle constrictor.

Relations.—It is covered by a thin membrane which surrounds the entire pharynx (bucco-pharyngeal fascia). *Behind*, it is in relation with the vertebral column and the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sterno-thyroid muscle; by its *internal surface*, with the Middle constrictor, the Stylo-pharyngeus, Palato-pharyngeus, the fibrous coat and mucous membrane of the pharynx. The internal laryngeal nerve and the laryngeal branch of the Superior Thyroid artery pass near the upper border, and the inferior, or recurrent laryngeal nerve, and the laryngeal branch of the Inferior Thyroid artery, beneath the lower border of this muscle, previous to their entering the larynx.

FIG. 208.—Muscles of the pharynx. External view.

Relations.—This muscle is separated from the Superior constrictor by the glosso-pharyngeal nerve and the Stylo-pharyngeus muscle and Stylo-hyoid ligament; and from the Inferior constrictor by the superior laryngeal nerve. *Behind*, it lies on the vertebral column, the Longus colli, and the Rectus capitis' anticus major. *On each side* it is in relation with the carotid vessels, the pharyngeal plexus, and some lymphatic glands. Near its origin it is covered by the Hyoglossus, from which it is separated by the lingual vessels. It lies upon the Superior constrictor, the Stylo-pharyngeus, the Palato-pharyngeus, the fibrous coat, and the mucous membrane of the pharynx.

The **Superior Constrictor** is a quadrilateral muscle, thinner and paler than the other constrictors, and situated at the upper part of the pharynx. It arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process, from the contiguous portion of the palate bone and the reflected tendon of the Tensor palati muscle, from the pterygo-maxillary ligament, from the alveolar process above the posterior extremity of the mylo-hyoid ridge, and by a few fibres from the side of the tongue. From these points the fibres curve backward, to be inserted into the median raphe, being also prolonged by means of a fibrous aponeurosis to the pharyngeal spine on the basilar process of the occipital bone. The superior fibres arch beneath the Levator palati and the Eustachian tube, the interval between the upper border of the muscle and the basilar process being deficient in muscular fibres and closed by the pharyngeal aponeurosis. This interval is known as the *sinus of Morgagni*.

Relations.—By its *outer surface*, with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the

internal jugular vein and pharyngeal venous plexus, the glosso-pharyngeal, pneumogastric, spinal accessory, hypoglossal, lingual, and sympathetic nerves, the Middle constrictor and Internal pterygoid muscles, the Styloid process, the Stylohyoid ligament, and the Stylo-pharyngeus. By its *internal surface*, with the Palato-pharyngeus, the tonsil, the fibrous coat and mucous membrane of the pharynx.

The **Stylo-pharyngeus** is a long, slender muscle, round above, broad and thin below. It arises from the inner side of the base of the styloid process, passes downward along the side of the pharynx between the Superior and Middle constrictors, and spreads out beneath the mucous membrane, where some of its fibres are lost in the Constrictor muscles; and others, joining with the Palato-pharyngeus, are inserted into the posterior border of the thyroid cartilage. The glosso-pharyngeal nerve runs on the outer side of this muscle, and crosses over it in passing forward to the tongue.

Relations.—*Externally*, with the Stylo-glossus muscle, the parotid gland, the external carotid artery, and the Middle constrictor; *internally*, with the internal carotid, the internal jugular vein, the Superior constrictor, Palato-pharyngeus, and mucous membrane.

Nerves.—The Constrictors are supplied by branches from the pharyngeal plexus, the Stylo-pharyngeus by the glosso-pharyngeal nerve, and the Inferior constrictor by an additional branch from the external laryngeal nerve and by the recurrent laryngeal.

Actions.—When deglutition is about to be performed, the pharynx is drawn upward and dilated in different directions, to receive the morsel propelled into it from the mouth. The Stylo-pharyngei, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upward and outward, and so increase its transverse diameter, its breadth in the antero-posterior direction being increased by the larynx and tongue being carried forward in their ascent. As soon as the morsel is received in the pharynx, the Elevator muscles relax, the bag descends, and the Constrictors contract upon the morsel, and convey it gradually downward into the œsophagus. Besides its action in deglutition, the pharynx also exerts an important influence in the modulation of the voice, especially in the production of the higher tones.

6. Palatal Region.

Levator palati.
Tensor palati.
Azygos uvulæ.

Palato-glossus.
Palato-pharyngeus.
Salpingo-pharyngeus.

Dissection (Fig. 209).—Lay open the pharynx from behind by a vertical incision extending from its upper to its lower part, and partially divide the occipital attachment by a transverse incision on each side of the vertical one; the posterior surface of the soft palate is then exposed. Having fixed the uvula so as to make it tense, the mucous membrane and glands should be carefully removed from the posterior surface of the soft palate, and the muscles of this part are at once exposed.

The **Levator palati** is a long, thick, rounded muscle, placed on the outer side of the posterior nares. It arises from the under surface of the apex of the petrous portion of the temporal bone, and from the inner surface of the cartilaginous portion of the Eustachian tube; after passing into the pharynx, above the upper concave margin of the Superior constrictor, it passes obliquely downward and inward, its fibres spreading out in the soft palate as far as the middle line, where they blend with those of the opposite side.

Relations.—*Externally*, with the Tensor palati and Superior constrictor and Eustachian tube; *internally*, with the mucous membrane of the pharynx; *posteriorly*, with the posterior fasciculus of the Palato-pharyngeus, the Azygos uvulæ, and the mucous lining of the soft palate.

The **Circumflexus** or **Tensor palati** is a broad, thin, ribbon-like muscle, placed on the outer side of the Levator palati, and consisting of a vertical and a horizontal

portion. The vertical portion arises by a flat lamella from the scaphoid fossa at the base of the internal pterygoid plate; from the spine of the sphenoid and the outer side of the cartilaginous portion of the Eustachian tube: descending vertically between the internal pterygoid plate and the inner surface of the Internal pterygoid muscle, it terminates in a tendon, which winds round the hamular process, being retained in this situation by some of the fibres of origin of the Internal pterygoid muscle. Between the hamular process and the tendon is a small bursa. The tendon or horizontal portion then passes horizontally inward, and is inserted into a broad aponeurosis, the *palatine aponeurosis*, and into the transverse ridge on the horizontal portion of the palate bone.

FIG. 209.—Muscles of the soft palate, the pharynx being laid open from behind.

Relations.—*Externally*, with the Internal pterygoid; *internally*, with the Levator palati, from which it is separated by the Eustachian tube and Superior constrictor, and with the internal pterygoid plate. In the soft palate its tendon and the palatine aponeurosis are anterior to those of the Levator palati, being covered by the Palato-glossus and the mucous membrane.

Palatine Aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm, fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally, it is continuous with the pharyngeal aponeurosis.

The **Azygos uvulæ** is not a single muscle, as would be inferred from its name, but a pair of narrow cylindrical fleshy fasciculi placed on either side of the median line of the soft palate. Each muscle arises from the posterior nasal spine of the palate bone and from the contiguous tendinous aponeurosis of the soft palate, and descends to be inserted into the uvula.

Relations.—*Anteriorly*, with the tendinous expansion of the Levatores palati; *behind*, with the posterior fasciculus of the Palato-pharyngeus and the mucous membrane.

The two next muscles are exposed by removing the mucous membrane from the pillars of the fauces throughout nearly their whole extent.

The **Palato-glossus** (**Constrictor isthmi faucium**) is a small fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the anterior pillar of the soft palate. It arises from the anterior surface of the soft palate on each side of the uvula, and, passing downward, forward, and outward in front of the tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transversus linguæ. In the soft palate the fibres of this muscle are continuous with those of the muscle of the opposite side.

The **Palato-pharyngeus** is a long, fleshy fasciculus, narrower in the middle than at either extremity, forming, with the mucous membrane covering its surface, the posterior pillar of the soft palate. It is separated from the Palato-glossus by an angular interval, in which the tonsil is lodged. It arises from the soft palate by an expanded fasciculus, which is divided into two parts by the Levator palati and Azygos uvulæ. The *posterior fasciculus* lies in contact with the mucous membrane, and also joins with the corresponding muscle in the middle line; the *anterior fasciculus*, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing outward and downward behind the tonsil, the Palato-pharyngeus joins the Stylo-pharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx, and others passing across the middle line posteriorly to decussate with the muscle of the opposite side.

Relations.—In the soft palate its *posterior surface* is covered by mucous membrane, from which it is separated by a layer of palatine glands. By its *anterior surface* it is in relation with the Tensor palati. Where it forms the posterior pillar of the fauces it is covered by mucous membrane, excepting on its outer surface. In the *pharynx* it lies between the mucous membrane and the Constrictor muscles.

The **Salpingo-pharyngeus**.—This muscle arises from the inferior part of the Eustachian tube near its orifice; it passes downward and blends with the posterior fasciculus of the Palato-pharyngeus.

In a dissection of the soft palate from its posterior or nasal surface to its anterior or oral surface, the muscles would be exposed in the following order: viz. the posterior fasciculus of the Palato-pharyngeus, covered over by the mucous membrane reflected from the floor of the nasal fossæ; the Azygos uvulæ; the Levator palati; the anterior fasciculus of the Palato-pharyngeus; the aponeurosis of the Tensor palati, and the Palato-glossus covered over by a reflection from the oral mucous membrane.

Nerves.—The Tensor palati is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the internal branch of the spinal accessory, whose fibres are distributed along with certain branches of the pneumogastric through the pharyngeal plexus.¹ It is possible, however, that the Levator palati may be supplied by the facial through the Petrosal branch of the Vidian.

Actions.—During the *first stage* of deglutition the morsel of food is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx, and carried forward under it. During the *second stage* the entrance to the larynx is closed, not, as was formerly supposed, by the folding backward

¹ *Journal of Anatomy and Physiology*, vol. xxiii., p. 523.

of the epiglottis over it, but, as Anderson Stuart has shown, by the drawing forward of the arytenoid cartilages toward the cushion of the epiglottis—a movement produced by the contraction of the external thyro-arytenoid, the arytenoid, and aryteno-epiglottidean muscles.

The morsel of food after leaving the tongue passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance;¹ then the Palato-glossi muscles, the constrictors of the fauces, contract behind the food; the soft palate is slightly raised by the Levator palati, and made tense by the Tensor palati; and the Palato-pharyngei, by their contraction, pull the pharynx upward over the morsel of food, and at the same time come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented passing into the upper part of the pharynx or the posterior nares; at the same time the latter muscles form an inclined plane, directed obliquely downward and backward, along the under surface of which the morsel descends into the lower part of the pharynx. The Salpingo-pharyngeus raises the upper and lateral part of the pharynx—*i. e.* that part which is above the point where the Stylo-pharyngeus is attached to the pharynx.

Surgical Anatomy.—The muscles of the soft palate should be carefully dissected, the relations they bear to the surrounding parts especially examined, and their action attentively studied upon the dead subject, as the surgeon is required to divide one or more of these muscles in the operation of staphylorrhaphy. Sir W. Fergusson was the first to show that in the congenital deficiency called *cleft palate* the edges of the fissure are forcibly separated by the action of the Levatores palati and Palato-pharyngei muscles, producing very considerable impediment to the healing process after the performance of the operation for uniting their margins by adhesion; he, consequently, recommended the division of these muscles as one of the most important steps in the operation. This he effected by an incision made with a curved knife introduced behind the soft palate. The incision is to be halfway between the hamular process and Eustachian tube, and perpendicular to a line drawn between them. This incision perfectly accomplishes the division of the Levator palati. The Palato-pharyngeus may be divided by cutting across the posterior pillar of the soft palate, just below the tonsil, with a pair of blunt-pointed curved scissors; and the anterior pillar may be divided also. To divide the Levator palati the plan recommended by Mr. Pollock is to be greatly preferred. The soft palate being put upon the stretch, a double-edged knife is passed through it just on the inner side of the hamular process and above the line of the Levator palati. The handle being now alternately raised and depressed, a sweeping cut is made along the posterior surface of the soft palate, and the knife withdrawn, leaving only a small opening in the mucous membrane on the anterior surface. If this operation is performed on the dead body and the parts afterward dissected, the Levator palati will be found completely divided. In the present day, however, this division of the muscles, as part of the operation of staphylorrhaphy, is not so much insisted upon. All tension is prevented by making longitudinal incisions on either side, parallel to the cleft and just internal to the hamular process, in such a position as to avoid the posterior palatine artery.

7. Anterior Vertebral Region.

Rectus capitis anticus major.

Rectus capitis lateralis.

Rectus capitis anticus minor.

Longus colli.

The *Rectus capitis anticus major* (Fig. 210), broad and thick above, narrow below, appears like a continuation upward of the *Scalenus anticus*. It arises by four tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and ascends, converging toward its fellow of the opposite side, to be inserted into the basilar process of the occipital bone.

Relations.—By its *anterior surface*, with the pharynx, the sympathetic nerve, and the sheath enclosing the internal and common carotid artery, internal jugular vein, and pneumogastric nerve; by its *posterior surface*, with the *Longus colli*, the *Rectus capitis anticus minor*, and the upper cervical vertebræ.

The *Rectus capitis anticus minor* is a short, flat muscle, situated immediately behind the upper part of the preceding. It arises from the anterior surface of the lateral mass of the atlas and from the root of its transverse process, and, passing

¹ Walton (quoted by A. Stuart) maintains that the epiglottis is not essential to the deglutition even of liquids.

obliquely upward and inward, is inserted into the basilar process immediately behind the preceding muscle.

Relations.—By its *anterior surface*, with the Rectus capitis anticus major; by its *posterior surface*, with the front of the occipito-atlantal articulation.

The **Rectus capitis lateralis** is a short, flat muscle, which arises from the upper surface of the transverse process of the atlas, and is inserted into the under surface of the jugular process of the occipital bone.

Relations.—By its *anterior surface*, with the internal jugular vein; by its *posterior surface*, with the vertebral artery. On its *outer side* lies the occipital artery; on its *inner side*, the suboccipital nerve.

FIG. 210.—The prevertebral muscles.

The **Longus colli** is a long, flat muscle, situated on the anterior surface of the spine, between the atlas and the third dorsal vertebra. It is broad in the middle, narrow and pointed at each extremity, and consists of three portions: a superior oblique, an inferior oblique, and a vertical portion. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebrae, and, ascending obliquely inward, is inserted by a narrow tendon into the tubercle on the anterior arch of the atlas. The *inferior oblique portion*, the smallest part of the muscle, arises from the front of the bodies of the first two or three dorsal vertebrae, and, ascending obliquely outward, is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The *vertical portion* lies directly on the front of the spine; it arises, below, from the front of the bodies of the upper three dorsal and lower three cervical vertebrae, and is inserted above into the front of the bodies of the second, third, and fourth cervical vertebrae above.

Relations.—By its *anterior surface*, with the prevertebral fascia, the pharynx, the œsophagus, sympathetic nerve, the sheath of the great vessels of the neck, the inferior thyroid artery, and recurrent laryngeal nerve; by its *posterior surface*, with the cervical and dorsal portions of the spine. Its *inner border* is separated from the opposite muscle by a considerable interval below, but they approach each other above.

8. Lateral Vertebral Region.

Scalenus anticus.

Scalenus medius.

Scalenus posticus.

The **Scalenus anticus** is a conical-shaped muscle, situated deeply at the side of the neck, behind the Sterno-mastoid. It arises from the anterior tubercles of the

FIG. 211.—Muscles of the neck. (From a preparation in the Museum of the Royal College of Surgeons of England.)

transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and, descending almost vertically, is inserted by a narrow, flat tendon into the Scalene

tubercle on the inner border and upper surface of the first rib. The lower part of this muscle separates the subclavian artery and vein, the latter being in front, and the former, with the brachial plexus, behind.

Relations.—*In front*, with the clavicle, the Subclavius, Sterno-mastoid, and Omo-hyoid muscles, the transversalis colli, the suprascapular and ascending cervical arteries, the subclavian vein, and the phrenic nerve; by its *posterior surface*, with the Scalenus medius, pleura, the subclavian artery, and brachial plexus of nerves. It is separated from the Longus colli, on the inner side, by the vertebral artery. On the anterior tubercles of the transverse processes of the cervical vertebræ, between the attachments of the Scalenus anticus and Longus colli, lies the ascending cervical branch of the inferior thyroid artery.

The Scalenus medius, the largest and longest of the three Scaleni, arises from the posterior tubercles of the transverse processes of the lower six cervical vertebræ, and, descending along the side of the vertebral column, is inserted by a broad attachment into the upper surface of the first rib, behind the groove for the subclavian artery, as far back as the tubercle. It is separated from the Scalenus anticus by a subclavian artery below and the cervical nerves above. The posterior thoracic, or nerve of Bell, is formed in the substance of the Scalenus medius and emerges from it. The nerve to the Rhomboids also pierces it.

Relations.—By its *anterior surface*, with the Sterno-mastoid; it is crossed by the clavicle, the Omo-hyoid muscle, subclavian artery, and the cervical nerves. To its *outer side* is the Levator anguli scapulæ and the Scalenus posticus muscle.

The Scalenus posticus, the smallest of the three Scaleni, arises, by two or three separate tendons, from the posterior tubercles of the transverse processes of the lower two or three cervical vertebræ, and, diminishing as it descends, is inserted by a thin tendon into the outer surface of the second rib, behind the attachment of the Serratus magnus. This is the most deeply placed of the three Scaleni, and is occasionally blended with the Scalenus medius.

Nerves.—The Rectus capitis anticus major and minor and the Rectus lateralis are supplied by the first cervical nerve, and from the loop formed between it and the second; the Longus colli and Scaleni, by branches from the anterior divisions of the lower cervical nerves (fifth, sixth, seventh, and eighth) before they form the brachial plexus. The Scalenus medius also receives a filament from the deep external branches of the cervical plexus.

Actions.—The Rectus anticus major and minor are the direct antagonists of the muscles at the back of the neck, serving to restore the head to its natural position after it has been drawn backward. These muscles also serve to flex the head, and, from their obliquity, rotate it, so as to turn the face to one or the other side. The Longus colli flexes and slightly rotates the cervical portion of the spine. The Scaleni muscles, when they take their fixed point from above, elevate the first and second ribs, and are, therefore, inspiratory muscles. When they take their fixed point from below, they bend the spinal column to one or the other side. If the muscles of both sides act, lateral movement is prevented, but the spine is slightly flexed. The Rectus lateralis, acting on one side, bends the head laterally.

Surface Form.—The muscles in the neck, with the exception of the Platysma myoides, are invested by the deep cervical fascia, which softens down their form, and is of considerable importance in connection with deep cervical abscesses and tumors, modifying the direction of their growth and causing them to extend laterally instead of toward the surface. The *Platysma myoides* does not influence surface form except it is in action, when it produces wrinkling of the skin of the neck, which is thrown into oblique ridges parallel with the fasciculi of the muscle. Sometimes this contraction takes place suddenly and repeatedly as a sort of spasmodic twitching, the result of a nervous habit. The *Sterno-cleido-mastoid* is the most important muscle of the neck as regards its surface form. If the muscle is put into action by drawing the chin downward and to the opposite shoulder, its surface form will be plainly outlined. The sternal origin will stand out as a sharply-defined ridge, while the clavicular origin will present a flatter and not so prominent an outline. The fleshy middle portion will appear as an oblique roll or elevation, with a thick rounded anterior border gradually becoming less marked above. On the opposite side—i. e. on the side to which the head is turned—the outline is lost, its place being occupied by an oblique groove in the integument. When the muscle is at rest its anterior border is still

visible, forming an oblique rounded ridge, terminating below in the sharp outline of the sternal head. The posterior border of the muscle does not show above the clavicular head. The anterior border is defined by drawing a line from the tip of the mastoid process to the sterno-clavicular joint. It is an important surface-marking in the operation of ligature of the common carotid artery and some other operations. Between the sternal and clavicular heads is a slight depression, most marked when the muscle is in action. This is bounded below by the prominent sternal extremity of the clavicle. Between the sternal origins of the two muscles is a V-shaped space, the *suprasternal notch*, more pronounced below, and becoming toned down above, where the Sterno-hyoid and Sterno-thyroid muscles, lying upon the trachea, become more prominent. Above the hyoid bone, in the middle line, the anterior belly of the *Digastric* to a certain extent influences surface form. It corresponds to a line drawn from the symphysis of the lower jaw to the side of the body of the hyoid bone, and renders this part of the hyo-mental region convex. In the posterior triangle of the neck, the posterior belly of the *Omo-hyoid*, when in action, forms a conspicuous object, especially in thin necks, presenting a cord-like form running across this region, almost parallel with, and a little above, the clavicle.

MUSCLES AND FASCIÆ OF THE TRUNK.

The muscles of the Trunk may be arranged in four groups, corresponding with the region in which they are situated.

- | | |
|-----------------|-------------------|
| I. The Back. | III. The Abdomen. |
| II. The Thorax. | IV. The Perinæum. |

I. MUSCLES OF THE BACK.

The muscles of the Back are very numerous, and may be subdivided into five layers:

FIRST LAYER.

Trapezius.
Latissimus dorsi.

Longissimus dorsi.
Spinalis dorsi.

Cervical Region.

SECOND LAYER.

Levator anguli scapulæ.
Rhomboides minor.
Rhomboides major.

Cervicalis ascendens.
Transversalis cervicis.
Trachelo-mastoid.
Complexus.
Biventer cervicis.
Spinalis colli.

THIRD LAYER.

Serratus posticus superior.
Serratus posticus inferior.
Splenius capitis.
Splenius colli.

FIFTH LAYER.

Semispinalis dorsi.
Semispinalis colli.
Multifidus spinæ.
Rotatores spinæ.
Supraspinales.
Interspinales.
Extensor coccygis.
Intertransversales.
Rectus capitis posticus major.
Rectus capitis posticus minor.
Obliquus capitis inferior.
Obliquus capitis superior.

FOURTH LAYER.

Sacral and Lumbar Regions.

Erector spinæ.

Dorsal Region.

Ilio-costalis.
Musculus accessorius ad ilio-costalem.

First Layer.

Trapezius.

Latissimus dorsi.

Dissection (Fig. 212).—Place the body in a prone position, with the arms extended over the sides of the table, and the chest and abdomen supported by several blocks, so as to render the muscles tense. Then make an incision along the middle line of the back from the occipital protuberance to the coccyx. Make a transverse incision from the upper end of this to

the mastoid process, and a third incision from its lower end, along the crest of the ilium to about its middle. This large intervening space should, for convenience of dissection, be subdivided by a fourth incision, extending obliquely from the spinous process of the last dorsal vertebra, upward and outward, to the acromion process. This incision corresponds with the lower border of the Trapezius muscle. The flaps of integument are then to be removed in the direction shown in the figure.

The **superficial fascia** is exposed upon removing the skin from the back. It forms a layer of considerable thickness and strength, in which a quantity of granular pinkish fat is contained. It is continuous with the superficial fascia in other parts of the body. The **deep fascia** is a dense fibrous layer attached to the occipital bone, the spines of the vertebræ, the crest of the ilium, and the spine of the scapula. It covers over the superficial muscles, forming sheaths for them, and in the neck forms the posterior part of the deep cervical fascia; in the thorax it is continuous with the deep fascia of the axilla and chest, and in the abdomen with that covering the abdominal muscles.

The **Trapezius** (Fig. 213) is a broad, flat, triangular muscle, placed immediately beneath the skin and fascia, and covering the upper and back part of the neck and shoulders. It arises from the external occipital protuberance and the inner third of the superior curved line of the occipital bone; from the ligamentum nuchæ, the spinous process of the seventh cervical, and those of all the dorsal vertebræ; and from the corresponding portion of the supraspinous ligament. From this origin the superior fibres proceed downward and outward, the inferior ones upward and outward, and the middle fibres horizontally, and are inserted, the superior ones into the outer third of the posterior border of the clavicle; the middle fibres into the inner margin of the acromion process, and into the superior lip of the posterior border or crest of the spine of the scapula; the inferior fibres converge near the scapula, and terminate in a triangular aponeurosis, which glides over a smooth surface at the inner extremity of the spine, to be inserted into a tubercle at the outer part of this smooth surface. The Trapezius is fleshy in the greater part of its extent, but tendinous at its origin and insertion. At its occipital origin it is connected to the bone by a thin fibrous lamina, firmly adherent to the skin, and wanting the lustrous, shining appearance of aponeuroses. At its origin from the spines of the vertebræ it is connected to the bones by means of a broad semi-elliptical aponeurosis, which occupies the space between the sixth cervical and the third dorsal vertebræ, and forms, with the aponeurosis of the opposite muscle, a tendinous ellipse. The rest of the muscle arises by numerous short tendinous fibres. If the Trapezius is dissected on both sides, the two muscles resemble a trapezium or diamond-shaped quadrangle; two angles corresponding to the shoulders; a third to the occipital protuberance; and the fourth to the spinous process of the last dorsal vertebra.

The clavicular insertion of this muscle varies as to the extent of its attachment; it sometimes advances as far as the middle of the clavicle, and may even become blended with the posterior edge of the Sternal-mastoid or overlap it. This should be borne in mind in the operation for tying the third part of the subclavian artery.

FIG. 212.—Dissection of the muscles of the back.

Rhomboideus minor; in the back, with the Rhomboideus major, Supraspinatus, Infraspinatus, and Vertebral aponeurosis (which separates it from the prolongations of the Erector spinæ), and the Latissimus dorsi. The spinal accessory nerve and the superficial cervical artery and branches from the third and fourth cervical nerves pass beneath the anterior border of this muscle. The anterior margin of its cervical portion forms the posterior boundary of the posterior triangle of the neck, the other boundaries being the Sterno-mastoid in front and the clavicle below.

The Ligamentum nuchæ (Fig. 213) is a fibrous membrane, which, in the neck, represents the supraspinous and interspinous ligaments of the lower vertebræ. It extends from the external occipital protuberance to the spinous process of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the external occipital crest, the posterior tubercle of the atlas, and the spinous process of each of the cervical vertebræ, so as to form a septum between the muscles on each side of the neck. In man it is merely the rudiment of an important elastic ligament, which, in some of the lower animals, serves to sustain the weight of the head.

The Latissimus dorsi is a broad flat muscle which covers the lumbar and the lower half of the dorsal regions, and is gradually contracted into a narrow fasciculus at its insertion into the humerus. It arises by tendinous fibres from the spinous processes of the six inferior dorsal vertebræ and from the posterior layer of the lumbar fascia (see page 342), by which it is attached to the spines of the lumbar and sacral vertebræ and to the supraspinous ligament. It also arises from the external lip of the crest of the ilium, behind the origin of the External oblique, and by fleshy digitations from the three or four lower ribs, which are interposed between similar processes of the External oblique muscle (Fig. 218, page 358). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upward, and the lower vertically upward, so as to converge and form a thick fasciculus, which crosses the inferior angle of the scapula, and occasionally receives a few fibres from it. The muscle then curves around the lower border of the Teres major, and is twisted upon itself, so that the superior fibres become at first posterior and then inferior, and the vertical fibres at first anterior and then superior. It then terminates in a short quadrilateral tendon, about three inches in length, which, passing in front of the tendon of the Teres major, is inserted into the bottom of the bicipital groove of the humerus, its insertion extending higher on the humerus than that of the tendon of the Pectoralis major. The lower border of the tendon of this muscle is united with that of the Teres major, the surfaces of the two being separated by a bursa; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula. This muscle at its insertion gives off an expansion to the deep fascia of the arm.

A muscular slip, *axillary arch*, varying from 3 to 4 inches in length, and from $\frac{1}{4}$ to $\frac{3}{4}$ of an inch in breadth, occasionally arises from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coraco-brachialis, or the fascia over the Biceps. The position of this abnormal slip is a point of interest in its relation to the axillary artery, as it crosses the vessel just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It may be easily recognized by the transverse direction of its fibres. Dr. Struther found it, in 8 out of 105 subjects, occurring seven times on both sides.

There is usually a fibrous slip which passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps. This is occasionally muscular, and is the representative of the *Dorso-epitrochlearis* muscle of apes.

Relations.—Its *superficial surface* is subcutaneous, excepting at its upper part, where it is covered by the Trapezius, and at its insertion, where its tendon is crossed by the axillary vessels and the brachial plexus of nerves. By its *deep surface* it is in relation with the Lumbar fascia, the Serratus posticus inferior, the lower external intercostal muscles and ribs, inferior angle of the scapula, Rhomboideus major, Infraspinatus, and Teres major. Its outer margin is

separated below from the External oblique by a small triangular interval, the triangle of Petit; and another triangular interval exists between its upper border and the margin of the Trapezius, in which the Rhomboideus major muscle is exposed.

Nerves.—The Trapezius is supplied by the spinal accessory, and by branches from the anterior divisions of the third and fourth cervical nerves: the Latissimus dorsi, by the middle or long subscapular nerve.

Second Layer.

Levator anguli scapulæ.

Rhomboideus minor.

Rhomboideus major.

Dissection.—The Trapezius must be removed, in order to expose the next layer; to effect this, detach the muscle from its attachment to the clavicle and spine of the scapula, and turn it back toward the spine.

The **Levator anguli scapulæ** is situated at the back part and side of the neck. It arises by tendinous slips from the transverse process of the atlas, and from the posterior tubercles of the transverse process of the second, third, and fourth cervical vertebræ; these, becoming fleshy, are united so as to form a flat muscle, which, passing downward and backward, is inserted into the posterior border of the scapula, between the superior angle and the triangular smooth surface at the root of the spine:

Relations.—By its *superficial surface*, with the integument, Trapezius, and Sterno-mastoid; by its *deep surface*, with the Splenius colli, Transversalis cervicis, Cervicalis ascendens, and Serratus posticus superior muscles, and with the posterior scapular artery and the nerve to the Rhomboids.

The **Rhomboideus minor** arises from the ligamentum nuchæ and spinous processes of the seventh cervical and first dorsal vertebræ. Passing downward and outward, it is inserted into the margin of the triangular smooth surface at the root of the spine of the scapula. This small muscle is usually separated from the Rhomboideus major by a slight cellular interval.

Relations.—By its *superficial (posterior) surface*, with the Trapezius; by its *deep surface*, with the same structures as the Rhomboideus major.

The **Rhomboideus major** is situated immediately below the preceding, the adjacent margins of the two being occasionally united. It arises by tendinous fibres from the spinous processes of the four or five upper dorsal vertebræ and the supraspinous ligament, and is inserted into a narrow tendinous arch attached above to the lower part of the triangular surface at the root of the spine; below, to the inferior angle, the arch being connected to the border of the scapula by a thin membrane. When the arch extends, as it occasionally does, but a short distance, the muscular fibres are inserted into the scapula itself.

Relations.—By its *superficial (posterior) surface*, with the Latissimus dorsi; by its *deep (anterior) surface*, with the Serratus posticus superior, posterior scapular artery, the vertebral aponeurosis which separates it from the prolongations from the Erector spinæ, the Intercostal muscles, and ribs.

Nerves.—The Rhomboid muscles are supplied by branches from the anterior division of the fifth cervical nerve; the Levator anguli scapulæ, by the anterior division of the third and fourth cervical nerves, and frequently by a branch from the nerve to the Rhomboids.

Actions.—The movements effected by the preceding muscles are numerous, as may be conceived from their extensive attachment. The whole of the Trapezius when in action retracts the scapula and braces back the shoulder; if the head is fixed, the upper part of the *Trapezius* will elevate the point of the shoulder, as in supporting weights; when the lower fibres are brought into action, they assist in depressing the bone. The middle and lower fibres of the muscle rotate the scapula, causing elevation of the acromion process. If the shoulders are fixed, both

Trapezii, acting together, will draw the head directly backward; or if only one acts, the head is drawn to the corresponding side.

The *Latissimus dorsi*, when it acts upon the humerus, depresses it, draws it backward, adducts, and at the same time rotates it inward. It is the muscle which is principally employed in giving a downward blow, as in felling a tree or in sabre practice. If the arm is fixed, the muscle may act in various ways upon the trunk; thus, it may raise the lower ribs and assist in forcible inspiration; or, if both arms are fixed, the two muscles may assist the Abdominal and great Pectoral muscles in suspending and drawing the whole trunk forward, as in climbing or walking on crutches.

The *Levator anguli scapulæ* raises the superior angle of the scapula, assisting the Trapezius in bearing weights or in shrugging the shoulders. If the shoulder be fixed, the *Levator anguli scapulæ* inclines the neck to the corresponding side and rotates it in the same direction. The Rhomboid muscles carry the inferior angle backward and upward, thus producing a slight rotation of the scapula upon the side of the chest, the Rhomboideus major acting especially on the lower angle of the scapula through the tendinous arch by which it is inserted. The Rhomboid muscles, acting together with the middle and inferior fibres of the Trapezius, will draw the scapula directly backward toward the spine.

Third Layer.

Serratus posticus superior.

Serratus posticus inferior.

Splenius { Splenius capitis.
Splenius colli.

Dissection.—To bring into view the third layer of muscles, remove the whole of the second, together with the *Latissimus dorsi*, by cutting through the *Levator anguli scapulæ* and Rhomboid muscles near their origin, and reflecting them downward, and by dividing the *Latissimus dorsi* in the middle by a vertical incision carried from its upper to its lower part, and reflecting the two halves of the muscle.

The *Serratus posticus superior* is a thin, flat, quadrilateral muscle situated at the upper and back part of the thorax. It arises by a thin and broad aponeurosis from the ligamentum nuchæ, and from the spinous processes of the last cervical and two or three upper dorsal vertebræ and from the supraspinous ligament. Inclining downward and outward, it becomes muscular, and is inserted, by four fleshy digitations into the upper borders of the second, third, fourth, and fifth ribs, a little beyond their angles.

Relations.—By its *superficial surface*, with the Trapezius, Rhomboidei, and *Levator anguli scapulæ*; by its *deep surface*, with the Splenius and the vertebral aponeurosis, which separates it from the prolongations of the Erector spinæ, and with the Intercostal muscles and ribs.

The *Serratus posticus inferior* is situated at the junction of the dorsal and lumbar regions; it is of an irregularly quadrilateral form, broader than the preceding, and separated from it by a considerable interval. It arises by a thin aponeurosis from the spinous processes of the last two dorsal and two or three upper lumbar vertebræ, and from the supraspinous ligaments. Passing obliquely upward and outward, it becomes fleshy, and divides into four flat digitations, which are inserted into the lower borders of the four lower ribs, a little beyond their angles. The thin aponeurosis of origin is intimately blended with the lumbar fascia.

Relations.—By its *superficial surface*, with the *Latissimus dorsi*. By its *deep surface*, with the Erector spinæ, ribs, and Intercostal muscles. Its upper margin is continuous with the vertebral aponeurosis.

The *Vertebral aponeurosis* is a thin, fibrous lamina, extending along the whole length of the back part of the thoracic region, serving to bind down the long Extensor muscles of the back which support the spine and head, and separate them from those muscles which connect the spine to the upper extremity. It consists of longitudinal and transverse fibres blended together, forming a thin lamella, which is attached in the median line to the spinous processes of the dorsal vertebræ; ex-

ternally, to the angles of the ribs; and below, to the upper border of the Serratus posticus inferior and a portion of the lumbar fascia, which gives origin to the Latissimus dorsi; above, it passes beneath the Serratus posticus superior and the Splenius, and blends with the deep fascia of the neck.

The *Lumbar fascia* or *aponeurosis* (Fig. 213), which may be regarded as the posterior aponeurosis of the Transversalis abdominis muscle, consists of three laminæ, which are attached as follows: the posterior layer, to the spines of the lumbar and sacral vertebræ and their supraspinous ligaments; the middle, to the tips of the transverse processes of the lumbar vertebræ and their intertransverse ligaments; the anterior, to the roots of the lumbar transverse processes. The posterior layer is continued above as the vertebral aponeurosis, while inferiorly it is fixed to the outer lip of the iliac crest. With this layer are blended the aponeurotic origin of the Serratus posticus inferior and part of that of the Latissimus dorsi. The middle layer is attached above to the last rib, and below to the iliac crest; the anterior layer is fixed below to the ilio-lumbar ligament and iliac crest; while above it is thickened to form the external arcuate ligament of the diaphragm, and stretches from the tip of the last rib to the transverse process of the first or second lumbar vertebra. These three layers, together with the vertebral column, enclose two spaces, the posterior of which is occupied by the Erector spinæ muscle, and the anterior by the Quadratus lumborum.

Now detach the Serratus posticus superior from its origin, and turn it outward, when the Splenius muscle will be brought into view.

The **Splenius** is situated at the back of the neck and upper part of the dorsal region. At its origin it is a single muscle, narrow, and pointed in form; but it soon becomes broader, and divides into two portions, which have separate insertions. It arises, by tendinous fibres, from the lower half of the ligamentum nuchæ, from the spinous processes of the last cervical and of the six upper dorsal vertebræ, and from the supraspinous ligament. From this origin the fleshy fibres proceed obliquely upward and outward, forming a broad flat muscle, which divides as it ascends into two portions, the Splenius capitis and Splenius colli.

The **Splenius capitis** is inserted into the mastoid process of the temporal bone, and into the rough surface on the occipital bone just beneath the superior curved line.

The **Splenius colli** is inserted, by tendinous fasciculi, into the posterior tubercles of the transverse processes of the two or three upper cervical vertebræ.

The Splenius is separated from its fellow of the opposite side by a triangular interval, in which is seen the Complexus.

Relations.—By its *superficial surface*, with the Trapezius, from which it is separated below by the Rhomboidei and the Serratus posticus superior. It is covered at its insertion by the Sterno-mastoid, and at the lower and back part of the neck by the Levator anguli scapulæ; by its *deep surface*, with the Spinalis dorsi, Longissimus dorsi, Semispinalis colli, Complexus, Trachelo-mastoid, and Transversalis cervicis.

Nerves.—The Splenius is supplied from the external branches of the posterior divisions of the cervical nerves; the Serratus posticus superior is supplied by the external branches of the posterior divisions of the upper dorsal nerves; the Serratus posticus inferior by the external branches of the posterior divisions of the lower dorsal nerves.

Actions.—The Serrati are respiratory muscles. The Serratus posticus superior elevates the ribs; it is therefore an inspiratory muscle; while the Serratus inferior draws the lower ribs downward and backward, and thus elongates the thorax. It also fixes the lower ribs, thus aiding the downward action of the diaphragm and resisting the tendency which it has to draw the lower ribs upward and forward. It must therefore be regarded as a muscle of inspiration. This muscle is also probably a tensor of the vertebral aponeurosis. The Splenii muscles of the two sides, acting together, draw the head directly backward, assisting the Trapezius

and Complexus; acting separately, they draw the head to one or the other side, and slightly rotate it, turning the face to the same side. They also assist in supporting the head in the erect position.

Fourth Layer.

I. Erector spinæ.

a. Outer Column.
 Ilio-costalis.
 Musculus accessorius.
 Cervicalis ascendens.

b. Middle Column.
 Longissimus dorsi.
 Transversalis cervicis.
 Trachelo-mastoid.

c. Inner Column.

Spinalis dorsi.

II. Complexus.

Dissection.—To expose the muscles of the fourth layer, remove entirely the Serrati and the vertebral and lumbar fasciæ. Then detach the Splenius by separating its attachment to the spinous processes and reflecting it outward.

The **Erector spinæ** (Fig. 214) and its prolongations in the dorsal and cervical regions fill up the vertebral groove on each side of the spine. It is covered in the lumbar region by the lumbar fascia; in the dorsal region, by the Serrati muscles and the vertebral aponeurosis; and in the cervical region, by a layer of cervical fascia continued beneath the Trapezius and the Splenius. This large muscular and tendinous mass varies in size and structure at different parts of the spine. In the sacral region the Erector spinæ is narrow and pointed, and its origin chiefly tendinous in structure. In the lumbar region the muscle becomes enlarged, and forms a large fleshy mass. In the dorsal region it subdivides into two parts, which gradually diminish in size as they ascend to be inserted into the vertebræ and ribs.

The Erector spinæ arises from the anterior surface of a very broad and thick tendon, which is attached, internally, to the spines of the sacrum, to the spinous processes of the lumbar and the eleventh and twelfth dorsal vertebræ, and the supraspinous ligament; externally, to the back part of the inner lip of the crest of the ilium, and to the series of eminences on the posterior part of the sacrum, which represents the transverse processes, where it blends with the great sacro-sciatic and posterior sacro-iliac ligaments. Some of its fibres are continuous with the fibres of origin of the Gluteus maximus. The muscular fibres form a single large fleshy mass, bounded in front by the transverse processes of the lumbar vertebræ and by the middle lamella of the lumbar fascia. Opposite the last rib it divides into two parts, the Ilio-costalis and the Longissimus dorsi; the Spinalis dorsi is given off from the latter in the upper dorsal region.

The **Ilio-costalis** (*Sacro-lumbalis*), the external portion of the Erector spinæ, is inserted, generally, by six or seven flattened tendons into the inferior borders of the angles of the six or seven lower ribs. The number of the tendons of this muscle is, however, very variable, and therefore the number of ribs into which it is inserted. Frequently it is found to possess nine or ten tendons, and sometimes as many tendons as there are ribs, and is then inserted into the angles of all the ribs. If this muscle is reflected outward, it will be seen to be reinforced by a series of muscular slips which arise from the angles of the ribs; by means of these the Ilio-costalis is continued upward to the upper ribs and cervical portion of the spine. The accessory portions form two additional muscles, the Musculus accessorius and the Cervicalis ascendens.

The **Musculus accessorius ad ilio-costalem** arises, by separate flattened tendons, from the upper borders of the angles of the six lower ribs: these become muscular, and are finally inserted, by separate tendons, into the upper borders of the angles

FIG. 214.—Muscles of the back. Deep layers.

of the six upper ribs and into the back of the transverse process of the seventh cervical vertebra.

The **Cervicalis ascendens**¹ is the continuation of the Accessorius upward into the neck; it is situated on the inner side of the tendons of the Accessorius, arising from the angles of the four or five upper ribs, and is inserted by a series of slender tendons into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ.

The **Longissimus dorsi** is the middle and largest portion of the Erector spinæ. In the lumbar region, where it is as yet blended with the Ilio-costalis, some of the fibres are attached to the whole length of the posterior surface of the transverse processes and the accessory processes of the lumbar vertebræ, and to the middle layer of the lumbar fascia. In the dorsal region, the Longissimus dorsi is inserted, by long thin tendons, into the tips of the transverse processes of all the dorsal vertebræ, and into from seven to eleven of the lower ribs between their tubercles and angles. This muscle is continued upward to the cranium and cervical portion of the spine by means of two additional muscles, the Transversalis cervicis and Trachelo-mastoid.

The **Transversalis cervicis** or **colli**, placed on the inner side of the Longissimus dorsi, arises by long thin tendons from the summits of the transverse processes of the six upper dorsal vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ, from the second to the sixth inclusive.

The **Trachelo-mastoid** lies on the inner side of the preceding, between it and the Complexus muscle. It arises, by tendons, from the transverse processes of the five or six upper dorsal vertebræ, and the articular processes of the three or four lower cervical. The fibres form a small muscle, which ascends to be inserted into the posterior margin of the mastoid process, beneath the Splenius and Serno-mastoid muscles. This small muscle is almost always crossed by a tendinous intersection near its insertion into the mastoid process.²

The **Spinalis dorsi** connects the spinous processes of the upper lumbar and the dorsal vertebræ together by a series of muscular and tendinous slips which are intimately blended with the Longissimus dorsi. It is situated at the inner side of the Longissimus dorsi, arising, by three or four tendons, from the spinous processes of the first two lumbar and the last two dorsal vertebræ: these, uniting, form a small muscle, which is inserted, by separate tendons, into the spinous processes of the dorsal vertebræ, the number varying from four to eight. It is intimately united with the Semispinalis dorsi, which lies beneath it.

The **Spinalis colli** is a small muscle, connecting together the spinous processes of the cervical vertebræ, and analogous to the Spinalis dorsi in the dorsal region. It varies considerably in its size and in its extent of attachment to the vertebræ, not only in different bodies, but on the two sides of the same body. It usually arises by fleshy or tendinous slips, varying from two to four in number, from the spinous processes of the fifth, sixth, and seventh cervical vertebræ, and occasionally from the first and second dorsal, and is inserted into the spinous process of the axis, and occasionally into the spinous processes of the two vertebræ below it. This muscle was found absent in five cases out of twenty-four.

Relations.—The Erector spinæ and its prolongations are bound down to the vertebræ and ribs in the lumbar and dorsal regions by the lumbar fascia and the vertebral aponeurosis. The inner part of these muscles covers the muscles of the fifth layer. In the neck they are in relation, by their *superficial surface*, with the Trapezius and Splenius; by their *deep surface*, with the Semispinalis dorsi et colli and the Recti and Obliqui.

The **Complexus** is a broad thick muscle, situated at the upper and back part of the neck, beneath the Splenius, and internal to the Transversalis cervicis and

¹ This muscle is sometimes called "Cervicalis descendens." The student should remember that these long muscles take their fixed point from above or from below, according to circumstances.

² These two muscles (Transversalis cervicis and Trachelo-mastoid) are sometimes described as one, having a common origin, but dividing above at their insertion. The Trachelo-mastoid is then termed the *Transversalis capitis*.

Trachelo-mastoid. It arises, by a series of tendons, from the tips of the transverse processes of the upper six or seven dorsal and the last cervical vertebræ, and from the articular processes of the three cervical above this. The tendons, uniting, form a broad muscle, which passes obliquely upward and inward, and is inserted into the innermost depression between the two curved lines of the occipital bone. This muscle, about its middle, is traversed by a transverse tendinous intersection. The *Biventer cervicis* is a small fasciculus, situated on the inner side of the preceding, and in the majority of cases blended with it; it has received its name from having a tendon intervening between two fleshy bellies. It is sometimes described as a part of the Complexus. It arises by from two to four tendinous slips, from the transverse processes of as many of the upper dorsal vertebræ, and is inserted, on the inner side of the Complexus, into the superior curved line of the occipital bone.

Relations.—The Complexus is covered by the Splenius and the Trapezius. It lies on the Rectus capitis posticus major and minor, the Obliquus capitis superior and inferior, and on the Semispinalis colli, from which it is separated by the profunda cervicis artery, the princeps cervicis artery, and branches of the posterior primary divisions of the cervical nerves. The Biventer cervicis is separated from its fellow of the opposite side by the ligamentum nuchæ.

Fifth Layer.

Semispinalis dorsi.	Extensor coccygis.
Semispinalis colli.	Intertransversales.
Multifidus spinæ.	Rectus capitis posticus major.
Rotatores spinæ.	Rectus capitis posticus minor.
Supraspinales.	Obliquus capitis inferior.
Interspinales.	Obliquus capitis superior.

Dissection.—Remove the muscles of the preceding layer by dividing and turning aside the Complexus; then detach the Spinalis and Longissimus dorsi from their attachments, divide the Erector spinæ at its connection below to the sacral and lumbar spines, and turn it outward. The muscles filling up the interval between the spinous and transverse processes are then exposed.

The **Semispinalis dorsi** (Fig. 214) consists of thin, narrow, fleshy fasciculi interposed between tendons of considerable length. It arises by a series of small tendons from the transverse processes of the lower dorsal vertebræ, from the tenth or eleventh to the fifth or sixth; and is inserted, by five or six tendons, into the spinous processes of the upper four dorsal and lower two cervical vertebræ.

The **Semispinalis colli**, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six dorsal vertebræ, and is inserted into the spinous processes of four cervical vertebræ, from the axis to the fifth cervical. The fasciculus connected with the axis is the largest, and chiefly muscular in structure.

Relations.—By their *superficial surface*, from below upward, with the Spinalis dorsi, Longissimus dorsi, Splenius, Complexus, the profunda cervicis artery, the princeps cervicis artery, and the internal branches of the posterior divisions of the first, second, and third cervical nerves; by their *deep surface*, with the Multifidus spinæ.

The **Multifidus spinæ** consists of a number of fleshy and tendinous fasciculi which fill up the groove on either side of the spinous processes of the vertebræ, from the sacrum to the axis. In the sacral region these fasciculi arise from the back of the sacrum, as low as the fourth sacral foramen, and from the aponeurosis of origin of the Erector spinæ; from the inner surface of the posterior superior spine of the ilium and posterior sacro-iliac ligaments; in the lumbar regions, from the articular processes; in the dorsal region, from the transverse processes; and in the cervical region, from the articular processes of the three or four lower vertebræ. Each fasciculus, passing obliquely upward and inward, is inserted into the whole length of the spinous process of one of the vertebræ above. These fasciculi vary in length: the most superficial, the longest, pass from one vertebra to the

third or fourth above; those next in order pass from one vertebra to the second or third above; whilst the deepest connect two contiguous vertebræ.

Relations.—By its *superficial surface*, with the Longissimus dorsi, Spinalis dorsi, Semispinalis dorsi, and Semispinalis colli; by its *deep surface*, with the laminae and spinous processes of the vertebræ, and with the Rotatores spinæ in the dorsal region.

The **Rotatores spinæ** are found only in the dorsal region of the spine, beneath the Multifidus spinæ; they are eleven in number on each side. Each muscle is small and somewhat quadrilateral in form; it arises from the upper and back part of the transverse process, and is inserted into the lower border and outer surface of the lamina of the vertebra above, the fibres extending as far inward as the root of the spinous process. The first is found between the first and second dorsal; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end.

The **Supraspinales** consist of a series of fleshy bands which lie on the spinous processes in the cervical region of the spine.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spinous processes of the contiguous vertebræ, one on each side of the interspinous ligament. In the *cervical region* they are most distinct, and consist of six pairs, the first being situated between the axis and third vertebra, and the last between the last cervical and the first dorsal. They are small narrow bundles, attached, above and below, to the apices of the spinous processes. In the *dorsal region* they are found between the first and second vertebræ, and occasionally between the second and third; and below, between the eleventh and twelfth. In the *lumbar region* there are four pairs of these muscles in the intervals between the five lumbar vertebræ. There is also occasionally one in the interspinous space, between the last dorsal and first lumbar, and between the fifth lumbar and the sacrum.

The **Extensor coccygis** is a slender muscular fasciculus, occasionally present, which extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last bone of the sacrum or first piece of the coccyx, and passes downward to be inserted into the lower part of the coccyx. It is a rudiment of the Extensor muscle of the caudal vertebræ of the lower animals.

The **Intertransversales** are small muscles placed between the transverse processes of the vertebræ. In the *cervical region* they are most developed, consisting of rounded muscular and tendinous fasciculi, which are placed in pairs, passing between the anterior and the posterior tubercles of the transverse processes of two contiguous vertebræ, separated from one another by the anterior division of the cervical nerve, which lies in the groove between them. In this region there are seven pairs of these muscles, the first pair being between the atlas and axis, and the last pair between the seventh cervical and first dorsal vertebræ. In the *dorsal region* they are least developed, consisting chiefly of rounded tendinous cords in the intertransverse spaces of the upper dorsal vertebræ; but between the transverse processes of the lower three dorsal vertebræ, and between the transverse processes of the last dorsal and the first lumbar, they are muscular in structure. In the *lumbar region* they are arranged in pairs, on either side of the spine, one set occupying the entire interspace between the transverse processes of the lumbar vertebræ, the *intertransversales laterales*; the other set, *intertransversales mediales*, passing from the accessory process of one vertebra to the mammillary process of the next.

The **Rectus capitis posticus major** arises by a pointed tendinous origin from the spinous process of the axis, and, becoming broader as it ascends, is inserted into the inferior curved line of the occipital bone and the surface of bone immediately below it. As the muscles of the two sides pass upward and outward, they leave between them a triangular space, in which are seen the Recti capitis postici minores muscles.

Relations.—By its *superficial surface*, with the Complexus, and, at its insertion, with the Superior oblique; by its *deep surface*, with part of the Rectus capitis posticus minor, the posterior arch of the atlas, the posterior occipito-atlantal ligament, and part of the occipital bone.

The **Rectus capitis posticus minor**, the smallest of the four muscles in this region, is of a triangular shape; it arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, becoming broader as it ascends, is inserted into the rough surface beneath the inferior curved line, nearly as far as the foramen magnum, nearer to the middle line than the preceding.

Relations.—By its *superficial surface*, with the Complexus and the Rectus capitis posticus major; by its *deep surface*, with the posterior occipito-atlantal ligament.

The **Obliquus capitis inferior**, the larger of the two Oblique muscles, arises from the apex of the spinous process of the axis, and passes outward and slightly upward, to be inserted into the lower and back part of the transverse process of the atlas.

Relations.—By its *superficial surface*, with the Complexus and with the posterior division of the second cervical nerve, which crosses it; by its *deep surface*, with the vertebral artery and posterior atlanto-axial ligament.

The **Obliquus capitis superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas, joining with the insertion of the preceding, and, passing obliquely upward and inward, is inserted into the occipital bone, between the two curved lines, external to the Complexus.

Relations.—By its *superficial surface*, with the Complexus and Trachelo-mastoid and occipital artery. By its *deep surface*, with the posterior occipito-atlantal ligament.

The **Suboccipital Triangle**.—Between the two oblique muscles and the Rectus capitis posticus major a triangular interval exists, the *suboccipital triangle*. This triangle is bounded, above and internally, by the Rectus capitis posticus major; above and externally, by the Obliquus capitis superior; below and externally, by the Obliquus capitis inferior. It is covered in by a layer of dense fibro-fatty tissue, situated beneath the Complexus muscle. The floor is formed by the posterior occipito-atlantal ligament and the posterior arch of the atlas. It contains the vertebral artery, as it runs in a deep groove on the upper surface of the posterior arch of the atlas, and the posterior division of the suboccipital nerve.

Nerves.—The third, fourth, and fifth layers of the muscles of the back are supplied by the posterior primary divisions of the spinal nerves.

Actions.—When both the Spinales dorsi contract, they extend the dorsal region of the spine; when only one muscle contracts, it helps to bend the dorsal portion of the spine to one side. The Erector spinæ, comprising the Ilio-costalis and the Longissimus dorsi with their accessory muscles, serves, as its name implies, to maintain the spine in the erect posture; it also serves to bend the trunk backward when it is required to counterbalance the influence of any weight at the front of the body, as, for instance, when a heavy weight is suspended from the neck, or when there is any great abdominal distension, as in pregnancy or dropsy; the peculiar gait under such circumstances depends upon the spine being drawn backward by the counterbalancing action of the Erector spinæ muscles. The muscles which form the continuation of the Erector spinæ upward steady the head and neck, and fix them in the upright position. If the Ilio-costalis and Longissimus dorsi of one side act, they serve to draw down the chest and spine to the corresponding side. The Cervicales ascendens, taking their fixed points from the cervical vertebrae, elevate those ribs to which they are attached; taking their fixed points from the ribs, both muscles help to extend the neck; while one muscle bends the neck to its own side. The Transversalis cervicis, when both muscles act, taking their fixed point from below, bend the neck backward. The Trachelo-mastoid, when both muscles act, taking their fixed point from below, bend the head backward; while, if only one muscle acts, the face is turned to the side on which the muscle is acting, and then the head is bent to the shoulder. The two Recti

muscles draw the head backward. The *Rectus capitis posticus major*, owing to its obliquity, rotates the cranium, with the atlas, round the odontoid process, turning the face to the same side. The *Multifidus spinæ* acts successively upon the different parts of the spine; thus, the sacrum furnishes a fixed point from which the fasciculi of this muscle act upon the lumbar region; these then become the fixed points for the fasciculi moving the dorsal region, and so on throughout the entire length of the spine; it is by the successive contraction and relaxation of the separate fasciculi of this and other muscles that the spine preserves the erect posture without the fatigue that would necessarily have been produced had this position been maintained by the action of a single muscle. The *Multifidus spinæ*, besides preserving the erect position of the spine, serves to rotate it, so that the front of the trunk is turned to the side opposite to that from which the muscle acts, this muscle being assisted in its action by the *Obliquus externus abdominis*. The *Complexi* draw the head directly backward: if one muscle acts, it draws the head to one side, and rotates it so that the face is turned to the opposite side. The *Superior oblique* draws the head backward, and, from the obliquity in the direction of its fibres, will slightly rotate the cranium, turning the face to the opposite side. The *Obliquus capitis inferior* rotates the atlas, and with it the cranium, round the odontoid process, turning the face to the same side. The *Semispinales*, when the muscles of the two sides act together, help to extend the spine; when the muscles of one side only act, they rotate the dorsal and cervical parts of the spine, turning the body to the opposite side. The *Supraspinales* and *Interspinales* by approximating the spinous processes help to extend the spine. The *Intertransversales* approximate the transverse processes, and help to bend the spine to one side. The *Rotatores spinæ* assist the *Multifidus spinæ* to rotate the spine, so that the front of the trunk is turned to the side opposite to that from which the muscle acts.

Surface Forms.—The surface forms produced by the muscles of the back are numerous and difficult to analyze unless they are considered in systematic order. The most superficial layer, consisting of large strata of muscular substance, influences to a certain extent the surface form, and at the same time reveals the forms of the layers beneath. The *Trapezius* at the upper part of the back, and in the neck, covers over and softens down the outline of the underlying muscles. Its anterior border forms the posterior boundary of the posterior triangle of the neck. It forms a slight undulating ridge which passes downward and forward from the occiput to the junction of the middle and outer third of the clavicle. The tendinous ellipse formed by a part of the origin of the two muscles at the back of the neck is always to be seen as an oval depression, more marked when the muscle is in action. A slight dimple on the skin opposite the interval between the spinous processes of the third and fourth dorsal vertebræ marks the triangular aponeurosis by which the inferior fibres are inserted into the root of the spine of the scapula. From this point the inferior border of the muscle may be traced as an undulating ridge to the spinous process of the twelfth dorsal vertebra. In like manner, the *Latissimus dorsi* softens down and modulates the underlying structures at the lower part of the back and lower part of the side of the chest. In this way it modulates the outline of the *Erector spinæ*; of the *Serratus posticus inferior*, which is sometimes to be discerned through it, and is sometimes entirely obscured by it; of part of the *Serratus magnus* and *Superior oblique*, which it covers; and of the convex oblique ridges formed by the ribs with the intervening intercostal spaces. The anterior border of the muscle is the only part which gives a distinct surface form. This border may be traced, when the muscle is in action, as a rounded edge, starting from the crest of the ilium, and passing obliquely forward and upward to the posterior border of the axilla, where it combines with the *Teres major* in forming a thick rounded fold, the posterior boundary of the axillary space. The muscles in the second layer influence to a very considerable extent the surface form of the back of the neck and upper part of the trunk. The *Levator anguli scapulae* reveals itself as a prominent divergent line, running downward and outward, from the transverse processes of the upper cervical vertebræ to the angle of the scapula, covered over and toned down by the overlying *Trapezius*. The *Rhomboidei* produce, when in action, a vertical eminence between the vertebral border of the scapula and the spinal furrow, varying in intensity according to the condition of contraction or relaxation of the *Trapezius* muscle, by which they are for the most part covered. The lowermost part of the *Rhomboideus major* is uncovered by the *Trapezius*, and forms on the surface an oblique ridge running upward and inward from the inferior angle of the scapula. Of the muscles of the third layer of the back, the *Serratus posticus superior* does not in any way influence surface form. The *Serratus posticus inferior*, when in strong action, may occasionally be revealed as an elevation beneath the *Latissimus dorsi*. The *Splenii* by their divergence serve to broaden out the upper part of the back of the neck and produce a

local fulness in this situation, but do not otherwise influence surface form. Beneath all these muscles those of the fourth layer—the *Erector spinæ* and its continuations—influence the surface form in a decided manner. In the loins, the *Erector spinæ*, bound down by the lumbar fascia, forms a rounded vertical eminence, which determines the depth of the spinal furrow, and which below tapers to a point on the posterior surface of the sacrum and becomes lost there. In the back it forms a flattened plane which gradually becomes lost. In the neck the only part of this group of muscles which influences surface form is the *Trachelo-mastoid*, which produces a short convergent line across the upper part of the posterior triangle of the neck, appearing from under cover of the posterior border of the *Sterno-mastoid* and being lost below beneath the *Trapezius*.

2. MUSCLES AND FASCIÆ OF THE THORAX.

The muscles belonging exclusively to this region are few in number. They are the

Intercostales externi.	Triangularis sterni.
Intercostales interni.	Levatores costarum.
Infracostales.	Diaphragm.

Intercostal Fasciæ.—A thin but firm layer of fascia covers the outer surface of the External intercostal and the inner surface of the Internal intercostal muscles; and a third layer, the middle intercostal fascia, more delicate, is interposed between the two planes of muscular fibres. These are the intercostal fasciæ; they are best marked in those situations where the muscular fibres are deficient, as between the External intercostal muscles and sternum, in front, and between the Internal intercostals and spine, behind.

The **Intercostal muscles** (Fig. 230) are two thin planes of muscular and tendinous fibres, placed one over the other, filling up the intercostal spaces, and being directed obliquely between the margins of the adjacent ribs. They have received the name “external” and “internal” from the position they bear to one another. The tendinous fibres are longer and more numerous than the muscular; hence the walls of the intercostal spaces possess very considerable strength, to which the crossing of the muscular fibres materially contributes.

The **External Intercostals** are eleven in number on each side. They extend from the tubercles of the ribs, behind, to the commencement of the cartilages of the ribs, in front, where they terminate in a thin membrane, the anterior intercostal membrane, which is continued forward to the sternum. They arise from the lower border of each rib, and are inserted into the upper border of the rib below. In the two lowest spaces they extend to the end of the cartilages, and in the upper two or three spaces they do not quite extend to the ends of the ribs. Their fibres are directed obliquely downward and forward, in a similar direction with those of the External oblique muscle of the abdomen. They are thicker than the Internal intercostals.

Relations.—By their *outer surface*, with the muscles which immediately invest the chest—viz. the *Pectoralis major* and *minor*, *Serratus magnus*, and *Rhomboideus major*, *Serratus posticus superior* and *inferior*, *Scalenus posticus*, *Ilio-costalis*, *Longissimus dorsi*, *Cervicalis ascendens*, *Transversalis cervicis*, *Levatores costarum*, *Obliquus externus abdominis*, and the *Latissimus dorsi*; by their *internal surface*, with the middle intercostal fascia, which separates them from the intercostal vessels and nerve and the Internal intercostal muscles, and, behind, from the pleura.

The **Internal intercostals** are also eleven in number on each side. They commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and from the anterior extremities of the cartilages of the false ribs, and extend backward as far as the angles of the ribs, whence they are continued to the vertebral column by a thin aponeurosis, the posterior intercostal membrane. They arise from the ridge on the inner surface of each rib, as well as from the corresponding costal cartilage, and are inserted into the upper border of the rib below. Their fibres are directed obliquely downward and backward, passing in the opposite direction to the fibres of the External intercostal muscle.

Relations.—By their *external surface*, with the intercostal vessels and nerves and the External intercostal muscles; near the sternum, with the anterior inter-

costal membrane and the Pectoralis major. By their *internal surface*, with the pleura costalis, Triangularis sterni, and Diaphragm.

The **Infracostales** (subcostales) consist of muscular and aponeurotic fasciculi, which vary in number and length: they are placed on the inner surface of the ribs, where the Internal intercostal muscles cease; they arise from the inner surface of one rib, and are inserted into the inner surface of the first, second, or third rib below. Their direction is most usually oblique, like the Internal intercostals. They are most frequent between the lower ribs.

The **Triangularis sterni** (Fig. 215) is a thin plane of muscular and tendinous fibres, situated upon the inner wall of the front of the chest. It arises from the lower third of the posterior surface of the sternum, from the posterior surface of the ensiform cartilage, and from the sternal ends of the costal cartilages of the three

FIG. 215.—Posterior surface of sternum and costal cartilages, showing Triangularis sterni muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

or four lower true ribs. Its fibres diverge upward and outward, to be inserted by digitations into the lower border and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal in their direction, and are continuous with those of the Transversalis; those which succeed are oblique, whilst the superior fibres are almost vertical. This muscle varies much in its attachment, not only in different bodies, but on opposite sides of the same body.

Relations.—*In front*, with the sternum, ensiform cartilage, costal cartilages,

Internal intercostal muscles, and internal mammary vessels; *behind*, with the pleura, pericardium, and anterior mediastinum.

The **Levatores Costarum** (Fig. 214), twelve in number on each side, are small tendinous and fleshy bundles which arise from the extremities of the transverse processes of the seventh cervical and eleven upper dorsal vertebræ, and, passing obliquely downward and outward, are inserted into the upper border of the rib below them, between the tubercle and the angle. The Inferior levatores divide into two fasciculi, one of which is inserted as above described; the other fasciculus passes down to the second rib below its origin; thus, each of the lower ribs receives fibres from the transverse processes of two vertebræ.

Nerves.—The muscles of this group are supplied by the intercostal nerves.

The **Diaphragm** (*διάφραγμα*, a partition wall) (Fig. 216) is a thin, musculo-fibrous septum, consisting of muscular fibres externally, which arise from the circumference of the thoracic cavity and pass upward and inward to converge to a central tendon. It is placed obliquely at the junction of the upper with the middle third of the trunk, and, separating the thorax from the abdomen, forming the floor of the former cavity and the roof of the latter. It is elliptical, its longest diameter being from side to side, somewhat fan-shaped, the broad elliptical portion being horizontal, the narrow part, the *crura*, which represents the handle of the fan, vertical, and joined at right angles to the former. It is from this circumstance that some anatomists describe it as consisting of two portions, the upper or great muscle of the Diaphragm, and the lower or lesser muscle. It arises from the whole of the internal circumference of the thorax, being attached, in front, by fleshy fibres to the ensiform cartilage; on either side, to the inner surface of the cartilages and bony portions of the six or seven inferior ribs, interdigitating with the Transversalis; and behind, to two aponeurotic arches, named the *ligamentum arcuatum externum et internum*, and by the *crura*, to the lumbar vertebræ. The fibres from these sources vary in length: those arising from the ensiform appendix are very short and occasionally aponeurotic; those from the ligamenta arcuata, and more especially those from the cartilages of the ribs at the side of the chest, are longer, describe well-marked curves as they ascend, and finally converge to be inserted into the circumference of the central tendon. Between the sides of the muscular slip from the ensiform appendix and the cartilages of the adjoining ribs the fibres of the Diaphragm are deficient, the interval being filled by areolar tissue, covered on the thoracic side by the pleuræ; on the abdominal, by the peritoneum. This is, consequently, a weak point, and a portion of the contents of the abdomen may protrude into the chest, forming phrenic or diaphragmatic hernia, or a collection of pus in the mediastinum may descend through it, so as to point at the epigastrium. A triangular gap is sometimes seen between the fibres springing from the internal and those arising from the external arcuate ligament. When it exists, the kidney is separated from the pleura only by fatty and areolar tissue.

The *ligamentum arcuatum internum* is a tendinous arch, thrown across the upper part of the Psoas magnus muscle, on each side of the spine. It is connected, by one end, to the outer side of the body of the first or second lumbar vertebra, being continuous with the outer side of the tendon of the corresponding crus; and, by the other end, to the front of the transverse process of the first, and sometimes also to that of the second, lumbar vertebra.

The *ligamentum arcuatum externum* is the thickened upper margin of the anterior lamella of the lumbar fascia; it arches across the upper part of the Quadratus lumborum, being attached, by one extremity, to the front of the transverse process of the first lumbar vertebra, and, by the other, to the apex and lower margin of the last rib.

The Crura.—The Diaphragm is connected to the spine by two *crura* or *pillars*, which are situated on the bodies of the lumbar vertebræ, on each side of the aorta. The *crura*, at their origin, are tendinous in structure; the right crus, larger and longer than the left, arising from the anterior surface of the bodies and intervertebral substances of the three or four upper lumbar vertebræ; the left, from

the two upper; both blending with the anterior common ligament of the spine. These tendinous portions of the crura pass forward and inward, and gradually converge to meet in the middle line, forming an arch, beneath which passes the aorta, vena azygos major, and thoracic duct. From this tendinous arch muscular fibres arise, which diverge, the outermost portion being directed upward and outward to the central tendon; the innermost decussating in front of the aorta, and then diverging, so as to surround the œsophagus before ending in the central tendon. The fibres derived from the right crus are the most numerous and pass in front of those derived from the left.

The *Central or Cordiform Tendon* of the Diaphragm is a thin but strong tendinous aponeurosis, situated at the centre of the vault formed by the muscle,

FIG. 216.—The Diaphragm. Under surface.

immediately below the pericardium, with which it is partly blended. It is shaped somewhat like a trefoil leaf, consisting of three divisions, or leaflets, separated from one another by slight indentations. The right leaflet is the largest; the middle one, directed toward the ensiform cartilage, the next in size; and the left, the smallest. In structure, the tendon is composed of several planes of fibres which intersect one another at various angles, and unite into straight or curved bundles—an arrangement which affords it additional strength.

The *Openings* connected with the Diaphragm are three large and several smaller apertures. The former are the aortic, the œsophageal, and the opening for the vena cava.

The *aortic opening* is the lowest and the most posterior of the three large apertures connected with this muscle, being at the level of the first lumbar vertebra. It is situated slightly to the left of the middle line, immediately in front of the bodies of the vertebræ; and is, therefore, *behind* the Diaphragm, not

in it. It is an osseo-aponeurotic aperture, formed by a tendinous arch thrown across the front of the bodies of the vertebræ, from the crus on one side to that on the other, and transmits the aorta, vena azygos major, and thoracic duct. Sometimes the vena azygos major is transmitted upward through the right crus. Occasionally some tendinous fibres are prolonged across the bodies of the vertebræ from the inner part of the lower end of the crura, passing behind the aorta, and thus converting the opening into a fibrous ring.

The *œsophageal opening* is situated at the level of the tenth dorsal vertebra; it is elliptical in form, muscular in structure, and, formed by the decussating fibres of the two crura, is placed above, and, at the same time, anterior, and a little to the left of the preceding. It transmits the œsophagus and pneumogastric nerves and some small œsophageal arteries. The anterior margin of this aperture is occasionally tendinous, being formed by the margin of the central tendon.

The *opening for the vena cava* (*foramen quadratum*) is the highest, about on the level of the disc between the eighth and ninth dorsal vertebræ; it is quadrilateral in form, tendinous in structure, and placed at the junction of the right and middle leaflets of the central tendon, its margins being adherent to the wall of the inferior vena cava.

The *right crus* transmits the greater and lesser splanchnic nerves of the right side; the *left crus* transmits the greater and lesser splanchnic nerves of the left side, and the vena azygos minor. The gangliated cords of the sympathetic usually enter the abdominal cavity by passing behind the internal arcuate ligaments.

The *Serous Membranes* in relation with the Diaphragm are four in number: three lining its upper or thoracic surface; one, its abdominal. The three serous membranes on its upper surface are the pleura on either side and the serous layer of the pericardium, which covers the middle portion of the tendinous centre. The serous membrane covering its under surface is a portion of the general peritoneal membrane of the abdominal cavity.

The Diaphragm is arched, being convex toward the chest and concave to the abdomen. The *right portion* forms a complete arch from before backward, being accurately moulded over the convex surface of the liver, and having resting upon it the concave base of the right lung. The *left portion* is arched from before backward in a similar manner; but the arch is narrower in front, being encroached upon by the pericardium, and lower than the right, at its summit, by about three-quarters of an inch. It supports the base of the left lung, and covers the great end of the stomach, the spleen, and left kidney. At its circumference the Diaphragm is higher in the mesial line of the body than at either side; but in the middle of the thorax the central portion, which supports the heart, is on a lower level than the two lateral portions.

Nerves.—The Diaphragm is supplied by the phrenic nerves and lower intercostal nerves and phrenic plexus of the sympathetic.

Actions.—The Intercostals are the chief agents in the movement of the ribs in ordinary respiration. When the first rib is elevated and fixed by the Scaleni, the External intercostals raise the other ribs, especially their fore part, and so increase the capacity of the chest from before backward; at the same time they evert their lower borders, and so enlarge the thoracic cavity transversely. The Internal intercostals, at the side of the thorax, depress the ribs and invert their lower borders, and so diminish the thoracic cavity; but at the fore part of the chest these muscles assist the External intercostals in raising the cartilages.¹ The Levatores

¹ The view of the action of the Intercostal muscles given in the text is that which is taught by Hutchinson (*Cycl. of Anat. and Phys.*, art. "Thorax"), and is usually adopted in our schools. It is, however, much disputed. Hanberger believed that the External intercostals act as elevators of the ribs, or muscles of inspiration, while the Internal act in expiration. Haller taught that both sets of muscles act in common—viz. as muscles of inspiration—and this view is adopted by many of the best anatomists of the Continent, and appears supported by many observations made on the human subject under various conditions of disease, and on living animals after the muscles have been exposed under chloroform. The reader may consult an interesting paper by Dr. Cleland in the *Journal of Anat. and*

costarum assist the External intercostals in raising the ribs. The Triangularis sterni draws down the costal cartilages; it is therefore an expiratory muscle.

The Diaphragm is the principal muscle of inspiration. When in a condition of rest the muscle presents a domed surface, concave toward the abdomen; and consists of a circumferential muscular and a central tendinous part. When the muscular fibres contract, they become less arched, or nearly straight, and thus cause the central tendon to descend, and in consequence the level of the chest-wall is lowered, the vertical diameter of the chest being proportionally increased. In this descent the different parts of the tendon move unequally. The left leaflet descends to the greatest extent; the right to a less extent, on account of the liver; and the central leaflet the least, because of its connection to the pericardium. In descending the diaphragm presses on the abdominal viscera, and so to a certain extent causes a projection of the abdominal wall; but in consequence of these viscera not yielding completely, the central tendon becomes a fixed point, and enables the circumferential muscular fibres to act *from* it, and so elevate the lower ribs and expand the lower part of the thoracic cavity; and Duchenne has shown that the Diaphragm has the power of elevating the ribs, to which it is attached, by its contraction, if the abdominal viscera are *in situ*, but that if these organs are removed, this power is lost. When at the end of inspiration the Diaphragm relaxes, the thoracic walls return to their natural position in consequence of their elastic reaction and of the elasticity and weight of the displaced viscera.¹

In all expulsive acts the Diaphragm is called into action, to give additional power to each expulsive effort. Thus, before sneezing, coughing, laughing, and crying, before vomiting, previous to the expulsion of the urine and *fæces*, or of the *fœtus* from the womb, a deep inspiration takes place.

The height of the Diaphragm is constantly varying during respiration, the muscle being carried upward or downward from the average level; its height also varies according to the degree of distension of the stomach and intestines, and the size of the liver. After a forced expiration, the right arch is on a level, in front, with the fourth costal cartilage; at the side, with the fifth, sixth, and seventh ribs; and behind, with the eighth rib, the left arch being usually from one to two ribs' breadth below the level of the right one. In a forced inspiration, it descends from one to two inches; its slope would then be represented by a line drawn from the ensiform cartilage toward the tenth rib.

Muscles of Inspiration and Expiration.—The muscles which assist the action of the Diaphragm in ordinary tranquil inspiration are the Intercostals and the Levatores costarum, as above stated, and the Scaleni. When the need for more forcible action exists, the shoulders and the base of the scapula are fixed, and then the powerful muscles of forced inspiration come into play; the chief of these are the Trapezius, the Pectoralis minor, the Serratus posticus superior and inferior, and the Rhomboidei. The lower fibres of the Serratus magnus may possibly assist slightly in dilating the chest by raising and everting the ribs. The Sternomastoid also, when the head is fixed, assists in forced inspiration by drawing up the sternum and by fixing the clavicle, and thus affording a fixed point for the action of the muscles of the chest. The Ilio-costalis and Quadratus lumborum assist in forced inspiration by fixing the last rib (see page 367).

The ordinary action of expiration is hardly effected by muscular force, but results from a return of the walls of the thorax to a condition of rest, owing to their own elasticity and to that of the lungs. Forced expiratory actions are

Phys. No. II., May, 1867, p. 209, "On the Hutchinsonian Theory of the Action of the Intercostal Muscles," who refers also to Henle, Luschka, Budge, and Baumbler, *Observations on the Action of the Intercostal Muscles*, Erlangen, 1860. (In *New Syd. Soc.'s Year-Book* for 1861, p. 69.) Dr. W. W. Keen has come to the conclusion, from experiments made upon a criminal executed by hanging, that the External intercostals are muscles of expiration, as they pulled the ribs down, while the Internal intercostals pulled the ribs up and are muscles of inspiration (*Trans. Coll. Phys. Philadelphia*, Third Series, vol. i., 1875, p. 97).

¹ For a detailed description of the general relations of the Diaphragm, and its action, refer to Dr. Sibson's *Medical Anatomy*.

performed mainly by the flat muscles (*Obliqui* and *Transversalis*) of the abdomen, assisted also by the *Rectus*. Other muscles of forced expiration are the *Internal intercostals* and *Triangularis sterni* (as above mentioned).

3. MUSCLES OF THE ABDOMEN.

The muscles of the abdomen may be divided into two groups: 1. The superficial muscles of the abdomen; 2. The deep muscles of the abdomen.

1. Superficial Muscles.

The Muscles in this region are, the

Obliquus Externus.

Obliquus Internus.

Transversalis.

Rectus.

Pyramidalis.

Dissection (Fig. 217).—To dissect the abdominal muscles, make a vertical incision from the ensiform cartilage to the symphysis pubis; a second incision from the umbilicus obliquely upward and outward to the outer surface of the chest, as high as the lower border of the fifth or sixth rib; and a third, commencing midway between the umbilicus and pubes, transversely outward to the anterior superior iliac spine, and along the crest of the ilium as far as its posterior third. Then reflect the three flaps included between these incisions from within outward, in the lines of direction of the muscular fibres. If necessary, the abdominal muscles may be made tense by inflating the peritoneal cavity through the umbilicus.

The **Superficial fascia** of the abdomen consists, over the greater part of the abdominal wall, of a single layer of fascia, which contains a variable amount of fat; but as this layer approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands. The superficial layer (*fascia of Camper*) is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below it passes over Poupart's ligament, and is continuous with the outer

FIG. 217.—Dissection of abdomen.

layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color, and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward to be continuous with the superficial fascia of the perinæum. In the female this fascia is continued into the labia majora. The deeper layer (*fascia of Scarpa*) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on to the dorsum of the penis, forming the suspensory ligament; above, it is continuous with the superficial fascia over the rest of the trunk; below, it blends with the fascia lata of the thigh a little below Poupart's ligament; and below and internally it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the deep layer of the superficial fascia of the perinæum. In the female it is continued into the labia majora.

The **External or Descending Oblique muscle** (Fig. 218) is situated on the side and fore part of the abdomen; being the largest and the most superficial of the three flat muscles in this region. It is broad, thin, and irregularly quadrilateral, its muscular portion occupying the side, its aponeurosis the anterior wall, of the

abdomen. It arises, by eight fleshy digitations, from the external surface and lower borders of the eight inferior ribs; these digitations are arranged in an oblique line running downward and backward; the upper ones being attached close to the cartilages of the corresponding ribs; the lowest, to the apex of the cartilage of the last rib; the intermediate ones, to the ribs at some distance from their cartilages. The five superior serrations increase in size from above downward, and are received between corresponding processes of the *Serratus magnus*; the three lower ones diminish in size from above downward, receiving between them corresponding processes from the *Latissimus dorsi*. From these attachments, the fleshy fibres proceed in various directions. Those from the lowest ribs pass nearly vertically downward, to be inserted into the anterior half of the outer lip of the crest of the ilium; the middle and upper fibres, directed downward and forward, terminate in an aponeurosis, opposite a line drawn from the prominence of the ninth costal cartilage to the anterior superior spinous process of the ilium.

The **Aponeurosis of the External Oblique** is a thin, but strong membranous aponeurosis, the fibres of which are directed obliquely downward and inward. It is joined with that of the opposite muscle along the median line, covers the whole of the front of the abdomen; above, it is connected with the lower border of the *Pectoralis major*; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior spine of the ilium to the spine of the os pubis and the *linea ilio-pectinea*. In the median line it interlaces with the aponeurosis of the opposite muscle, forming the *linea alba*, which extends from the ensiform cartilage to the symphysis pubis.

That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward, and continuous below with the *fascia lata*; it is called *Poupart's ligament*. The portion which is reflected from Poupart's ligament at the spine of the os pubis along the pectineal line is called *Gimbernat's ligament*. From the point of attachment of the latter to the pectineal line, a few fibres pass upward and inward, behind the inner pillar of the ring, to the *linea alba*. They diverge as they ascend, and form a thin, triangular, fibrous layer, which is called the *triangular fascia of the abdomen*.

In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the *external abdominal ring*, formed by a separation of the fibres of the aponeurosis in this situation.

Relations.—By its *external surface*, with the superficial fascia, superficial epigastric and circumflex iliac vessels, and some cutaneous nerves; by its *internal surface*, with the Internal oblique, the lower part of the eight inferior ribs, and Intercostal muscles, the Cremaster, the spermatic cord in the male, and round ligament in the female. Its *posterior border*, extending from the last rib to the crest of the ilium, is fleshy throughout and free; it is occasionally overlapped by the *Latissimus dorsi*, though generally a triangular interval exists between the two muscles near the crest of the ilium, in which is seen a portion of the internal oblique. This triangle, *Petit's triangle*, is therefore bounded in front by the External oblique, behind by the *Latissimus dorsi*, below by the crest of the ilium, while its floor is formed by the Internal oblique (Fig. 213).

The following parts of the aponeurosis of the External oblique muscle require to be further described: viz., the external abdominal ring, the intercolumnar fibres and fascia, Poupart's ligament, Gimbernat's ligament, and the triangular fascia of the abdomen.

The External Abdominal Ring.—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the *External Abdominal Ring*. The aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the *intercolumnar*, which pass across

the upper angle of the ring, so as to increase its strength; and on each side, by the margins of the opening in the aponeurosis, which are called the columns or pillars of the ring.

The external pillar, which is at the same time inferior from the obliquity of its direction, is the stronger: it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved so as to form a kind of groove, upon which the spermatic cord rests. The internal or superior pillar

FIG. 218.—The External oblique muscle.

is a broad, thin, flat band which is attached to the front of the symphysis pubis, interlacing with its fellow of the opposite side, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male, and round ligament in the female: it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the greater frequency of inguinal hernia in men.

The **intercolumnar fibres** are a series of curved tendinous fibres, which arch

across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring, describing a curve with the convexity downward. They are much thicker and stronger at the outer margin of the external ring, where they are connected to the outer third of Poupart's ligament, than internally, where they are inserted into the linea alba. They are more strongly developed in the male than in the female. The intercolumnar fibres increase the strength of the lower part of the aponeurosis, and prevent the divergence of the pillars from one another.

These intercolumnar fibres as they pass across the external abdominal ring are themselves connected together by delicate fibrous tissue, thus forming a fascia, which as it is attached to the pillars of the ring covers it in, and is called the *intercolumnar fascia*. This *intercolumnar fascia* is continued down as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence it is also called the external spermatic fascia.

The sac of an inguinal hernia, in passing through the external abdominal ring, receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external abdominal ring and the limb is then extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense, and the external ring much contracted; if the limb is on the contrary flexed upon the pelvis and rotated inward, this aponeurosis will become lax and the external abdominal ring sufficiently enlarged to admit the finger with comparative ease: hence the patient should always be put in the latter position when the taxis is applied for the reduction of an inguinal hernia in order that the abdominal walls may be relaxed as much as possible.

Poupart's ligament, or the **crural arch**, is the lower border of the aponeurosis of the External oblique muscle, and extends from the anterior superior spine of the ilium to the pubic spine. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

Nearly the whole of the space included between the crural arch and the innominate bone is filled in by the parts which descend from the abdomen into the thigh. These will be referred to again on a subsequent page.

Gimbernat's ligament is that part of the aponeurosis of the External oblique muscle which is reflected upward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form with the base directed outward. Its base, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath, forming the inner boundary of the femoral ring. Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament. Its surfaces are directed upward and downward.

The **triangular fascia** of the abdomen is a layer of tendinous fibres of a triangular shape, which is attached by its apex to the pectineal line, where it is continuous with Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring, and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

Ligament of Cooper.—This is a strong ligamentous band, which was first described by Sir Astley Cooper. It extends upward and backward from the base of Gimbernat's ligament along the ilio-pectineal line, to which it is attached. It is strengthened by the fascia transversalis, by the pectineal aponeurosis, and by a

lateral expansion from the lower attachment of the linea alba (adminiculum lineæ albæ).

Dissection.—Detach the External oblique by dividing it across, just in front of its attachment to the ribs, as far as its posterior border, and separate it below from the crest of the ilium as far as the anterior superior spine; then separate the muscle carefully from the Internal oblique, which lies beneath, and turn it toward the opposite side.

The **Internal or Ascending oblique muscle** (Fig. 219), thinner and smaller than the preceding, beneath which it lies, is of an irregularly quadrilateral form,

FIG. 219.—The internal oblique muscle.

and situated at the side and fore part of the abdomen. It arises, by fleshy fibres, from the outer half of Poupart's ligament, being attached to the groove on its upper surface; from the anterior two-thirds of the middle lip of the crest of the ilium, and from the posterior lamella of the lumbar fascia. From this origin the fibres diverge: those from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord in the male and the round ligament in the female, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, to the extent of half an inch, forming what is known as the conjoined tendon of the Internal oblique and Transversalis; those from the anterior third of the iliac origin are horizontal in their direction, and, becoming tendinous along the lower fourth of the linea semilunaris, pass in front of the Rectus muscle to be inserted into the linea alba; those which arise from the middle third of the origin from the crest of the ilium pass obliquely upward and inward, and terminate in an aponeurosis

which divides at the outer border of the Rectus muscle into two lamellæ, which are continued forward, in front and behind this muscle, to the linea alba, the posterior lamella being also connected to the cartilages of the seventh, eighth, and ninth ribs; the most posterior fibres pass almost vertically upward, to be inserted into the lower borders of the cartilages of the three lower ribs, being continuous with the Internal intercostal muscles.

The conjoined tendon of the Internal oblique and Transversalis is inserted into the crest of the os pubis and pectineal line, immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia; or the hernia forces its way through the fibres of the conjoined tendon. The conjoined tendon is sometimes divided into an outer and an inner portion—the former being termed the *ligament of Hesselbach*; the latter, the *ligament of Henle*.

The aponeurosis of the Internal oblique is continued forward to the middle line of the abdomen, where it joins with the aponeurosis of the opposite muscle at the linea alba, and extends from the margin of the thorax to the os pubis. At the outer margin of the Rectus muscle this aponeurosis, for the upper three-fourths of its extent, divides into two lamellæ, which pass, one in front and the other behind the muscle, enclosing it in a kind of sheath, and reuniting on its inner border at the linea alba; the anterior layer is blended with the aponeurosis of the External oblique muscle; the posterior layer with that of the Transversalis. Along the lower fourth the aponeurosis passes altogether in front of the Rectus without any separation. Where the aponeurosis ceases to split, and passes altogether in front of the Rectus muscle, a deficiency is left in the sheath of the muscle behind; this is marked above by a sharp lunated margin having its concavity downward. This is known as the *semilunar fold of Douglas*.

Relations.—By its *external surface*, with the External oblique, Latissimus dorsi, spermatic cord, and external ring; by its *internal surface*, with the Transversalis muscle, the lower intercostal vessels and nerves, the ilio-hypogastric and the ilio-inguinal nerves. Near Poupart's ligament it lies on the fascia transversalis, internal ring, and spermatic cord. Its lower border forms the upper boundary of the inguinal canal.

The **Cremaster muscle** is a thin, muscular layer, composed of a number of fasciculi which arise from the inner part of Poupart's ligament, where its fibres are continuous with those of the Internal oblique and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external abdominal ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *fascia cremasterica*. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of foetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched fibres of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum. It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in

front. It is probable that under these circumstances the testis, in its descent, passed through instead of beneath the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal hernia. The Cremaster muscle is found only in the male, but almost constantly in the female a few muscular fibres may be seen on the surface of the round ligament, which correspond to this muscle, and in cases of oblique inguinal hernia in the female a considerable amount of muscular fibre may be found covering the sac.

Dissection.—Detach the Internal oblique in order to expose the Transversalis beneath. This may be effected by dividing the muscle, above, at its attachment to the ribs; below, at its connection with Poupart's ligament and the crest of the ilium; and behind, by a vertical incision extending from the last rib to the crest of the ilium. The muscle should previously be made tense by drawing upon it with the fingers of the left hand, and if its division is carefully effected, the cellular interval between it and the Transversalis, as well as the direction of the fibres of the latter muscle, will afford a clear guide to their separation; along the crest of the ilium the circumflex iliac vessels are interposed between them, and form an important guide in separating them. The muscle should then be thrown inward toward the linea alba.

The **Transversalis muscle** (Fig. 220), so called from the direction of its fibres, is the most internal flat muscle of the abdomen, being placed immediately beneath the Internal oblique. It arises by fleshy fibres from the outer third of Poupart's ligament; from the inner lip of the crest of the ilium for its anterior three-fourths; from the inner surface of the cartilages of the six lower ribs, interdigitating with the Diaphragm; and from the lumbar fascia, which may be regarded as the posterior aponeurosis of the muscle. (See page 342.) The muscle terminates in front in a broad aponeurosis, the lower fibres of which curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, the crest of the os pubis and pectineal line forming what is known as the conjoined tendon of the Internal oblique and Transversalis. Throughout the rest of its extent the aponeurosis passes horizontally inward, and is inserted into the linea alba, its upper three-fourths passing behind the Rectus muscle, blending with the posterior lamella of the Internal oblique; its lower fourth passing in front of the Rectus.

Relations.—By its *external surface*, with the Internal oblique, the lower intercostal nerves, and the inner surface of the cartilages of the lower ribs; by its *internal surface*, with the fascia transversalis, which separates it from the peritoneum. Its lower border forms the upper boundary of the inguinal canal.

Dissection.—To expose the Rectus muscle, open its sheath by a vertical incision extending from the margin of the thorax to the os pubis, and then reflect the two portions from the surface of the muscle, which is easily done, excepting at the lineæ transversæ, where so close an adhesion exists that the greatest care is requisite in separating them. Now raise the outer edge of the muscle, in order to examine the posterior layer of the sheath. By dividing the muscle in the centre, and turning its lower part downward, the point where the posterior wall of the sheath terminates in a thin curved margin will be seen.

The **Rectus abdominis** is a long flat muscle, which extends along the whole length of the front of the abdomen, being separated from its fellow of the opposite side by the linea alba. It is much broader, but thinner, above than below, and arises by two tendons, the external or larger being attached to the crest of the os pubis, the internal, smaller portion interlacing with its fellow of the opposite side, and being connected with the ligaments covering the front of the symphysis pubis. The fibres ascend, and the muscle is inserted by three portions of unequal size into the cartilages of the fifth, sixth, and seventh ribs. The upper portion, attached principally to the cartilage of the fifth rib, usually has some fibres of insertion into the anterior extremity of the rib itself. Some fibres are occasionally connected with the costo-xiphoid ligaments and side of the ensiform cartilage.

The Rectus muscle is traversed by tendinous intersections, three in number.

which have received the name of *lineæ transversæ*. One of these is usually situated opposite the umbilicus, and two above that point; of the latter, one corresponds to the extremity of the ensiform cartilage, and the other to the interval between the ensiform cartilage and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance, sometimes pass only halfway across

FIG. 220.—The Transversalis, Rectus, and Pyramidalis muscles.

it, and are intimately adherent in front to the sheath in which the muscle is enclosed. Sometimes one or two additional lines may be seen, one usually below the umbilicus; the position of the other, when it exists, is variable. These additional lines are for the most part incomplete.

The Rectus is enclosed in a sheath (Fig. 221) formed by the aponeuroses of the Oblique and Transversalis muscles, which are arranged in the following manner. When the aponeurosis of the Internal oblique arrives at the outer margin of the Rectus, it divides into two lamellæ, one of which passes in front of the Rectus,

blending with the aponeurosis of the External oblique; the other, behind it, blending with the aponeurosis of the Transversalis; and these, joining again at its inner border, are inserted into the linea alba. This arrangement of the aponeuroses exists along the upper three-fourths of the muscle: at the commencement of the lower fourth, the posterior wall of the sheath terminates in a thin curved margin, the *semilunar fold of Douglas*, the concavity of which looks downward toward the pubes; the aponeuroses of all three muscles passing in front of the Rectus without any separation. The extremities of the fold of Douglas descend as pillars to the os pubis. The inner pillar is attached to the symphysis pubis; the outer pillar, which is named by Braune the ligament of Hesselbach, passes downward as a distinct band on the inner side of the internal abdominal ring, and there its fibres divide into two sets, internal and external; the internal fibres are attached to the ascending ramus of the os pubis and the pectineal fascia; the external ones pass to the Psoas fascia, to the deep surface of Poupart's ligament, and to the tendon of the Transversalis on the outer side of the ring. The Rectus muscle, in the situation where its sheath is deficient, is separated from the peritoneum by the transversalis fascia.

FIG. 221.—A transverse section of the abdomen in the lumbar region.

The **Pyramidalis** is a small muscle, triangular in shape, placed at the lower part of the abdomen, in front of the Rectus, and contained in the same sheath with that muscle. It arises by tendinous fibres from the front of the os pubis and the anterior pubic ligament; the fleshy portion of the muscle passes upward, diminishing in size as it ascends, and terminates by a pointed extremity, which is inserted into the linea alba, midway between the umbilicus and the os pubis. This muscle is sometimes found wanting on one or both sides; the lower end of the Rectus then becomes proportionately increased in size. Occasionally it has been found double on one side, or the muscles of the two sides are of unequal size. Sometimes its length exceeds what is stated above.

Besides the Rectus and Pyramidalis muscles, the sheath of the Rectus contains the superior and deep epigastric arteries, the terminations of the lumbar arteries and of the lower intercostal arteries and nerves.

Nerves.—The abdominal muscles are supplied by the lower intercostal nerves. The Transversalis and Internal oblique also receive filaments from the hypogastric branch of the ilio-hypogastric and sometimes from the ilio-inguinal. The Cremaster is supplied by the genital branch of the Genito-crural.

In the description of the abdominal muscles mention has frequently been made of the linea alba, lineæ semilunares, and lineæ transversæ; when the dissection of the muscles is completed these structures should be examined.

The **linea alba** is a tendinous raphé seen along the middle line of the abdomen, extending from the ensiform cartilage to the symphysis pubis, to which it is attached. It is placed between the inner borders of the Recti muscles, and is formed by the blending of the aponeuroses of the Obliqui and Transversales muscles. It is narrow below, corresponding to the narrow interval existing between the Recti; but broader above, as these muscles diverge from one another in their ascent, becoming of considerable breadth after great distension of the abdomen from pregnancy or ascites. It presents numerous apertures for the passage of vessels and nerves: the largest of these is the umbilicus, which in the fœtus transmits the umbilical vessels, but in the adult is obliterated, the cicatrix being stronger than the neighboring parts; hence umbilical hernia occurs in the adult *near* the umbilicus, whilst in the fœtus it occurs *at* the umbilicus. The linea alba is in relation, in front, with the integument, to which it is adherent, especially at the umbilicus; behind, it is separated from the peritoneum by the transversalis fascia; and below, by the urachus, and the bladder when that organ is distended.

The **lineæ semilunares** are two curved tendinous lines placed one on each side of the linea alba. Each corresponds with the outer border of the Rectus muscle, extends from the cartilage of the ninth rib to the pubic spine, and is formed by the aponeurosis of the Internal oblique at its point of division to enclose the Rectus, where it is reinforced in front by the External oblique and behind by the Transversalis.

The **lineæ transversæ** are narrow transverse lines which intersect the Recti muscles, as already mentioned; they connect the lineæ semilunares with the linea alba.

Actions.—The abdominal muscles perform a threefold action:

When the pelvis and thorax are fixed, they compress the abdominal viscera, by constricting the cavity of the abdomen, in which action they are materially assisted by the descent of the diaphragm. By these means the fœtus is expelled from the uterus, the fæces from the rectum, the urine from the bladder, and the contents of the stomach in vomiting.

If the pelvis and spine are fixed, these muscles compress the lower part of the thorax, materially assisting expiration. If the pelvis alone is fixed, the thorax is bent directly forward when the muscles of both sides act, or to either side when those of the two sides act alternately, rotation of the trunk at the same time taking place to the opposite side.

If the thorax is fixed, these muscles, acting together, draw the pelvis upward, as in climbing; or, acting singly, they draw the pelvis upward, and bend the vertebral column to one side or the other. The Recti muscles, acting from below, depress the thorax, and consequently flex the vertebral column; when acting from above, they flex the pelvis upon the vertebral column. The Pyramidales are tensors of the linea alba.

The **fascia transversalis** is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the extra-peritoneal fat. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciæ. In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle, but it becomes thin and cellular as it ascends to the Diaphragm, and blends with the fascia covering this muscle. In front, it unites across the middle line with the fascia on the opposite side of the body, and behind it becomes lost in the fat which covers the posterior surfaces of the kidneys. Below, it has the following attachments: posteriorly, it is connected to the whole length of the crest of the ilium, between the attachments of the Transversalis and Iliacus muscles; between the anterior superior spine of the ilium and the femoral vessels it is connected to the posterior margin of Poupart's ligament, and is there continuous with the iliac fascia. Internal to the femoral vessels it is thin and attached to the os pubis and pectineal line, behind the conjoined tendon, with which it is united; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends in

front of them, forming the anterior wall of the crural sheath. Beneath Poupart's ligament it is strengthened by a band of fibrous tissue, which is only loosely connected to Poupart's ligament, and is specialized as the *deep crural arch*. The spermatic cord in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the *internal abdominal ring*. This opening is not visible externally, owing to a prolongation of the transversalis fascia on these structures, forming the *infundibuliform fascia*.

The **internal or deep abdominal ring** is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart's ligament. It is of an oval form, the extremities of the oval directed upward and downward, varies in size in different subjects, and is much larger in the male than in the female. It is bounded, above and externally, by the arched fibres of the Transversalis; below and internally, by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin funnel-shaped membrane, the *infundibuliform fascia*, is continued round the cord and testis, enclosing them in a distinct pouch.

When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The **inguinal or spermatic canal** contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal about an inch and a half in length, directed downward and inward, and placed parallel to and a little above Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded in front by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; behind, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; above, by the arched fibres of the Internal oblique and Transversalis; below, by Gimbernat's ligament, and by the union of the fascia transversalis with Poupart's ligament. The deep epigastric artery passes upward and inward behind the canal lying close to the inner side of the internal abdominal ring. The interval between this artery and the outer edge of the Rectus is named *Hesselbach's triangle*, the base of which is formed by Poupart's ligament.

That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called *oblique inguinal hernia*.

The Deep Crural Arch.—Curving over the vessels, just at the point where they become femoral, on the abdominal side of Poupart's ligament and loosely connected with it, is a thickened band of fibres called the *deep crural arch*. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath to be inserted by a broad attachment into the spine of the os pubis and ilio-pectineal line, behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not infrequently it is altogether wanting.

Surface Form.—The only two muscles of this group which have any considerable influence on surface form are the External oblique and Rectus muscles of the abdomen. With regard to the External oblique, the upper digitations of its origin from the ribs are well marked, intermingled with the serrations of the Serratus magnus; the lower digitations are not visible, being covered by the thick border of the Latissimus dorsi. Its attachment to the crest of the ilium, in conjunction with the Internal oblique, forms a thick oblique roll, which determines the iliac furrow. Sometimes on the front of the lateral region of the abdomen an undulating outline marks the spot where the muscular fibres terminate and the aponeurosis commences. The outer border of the Rectus is defined by the *linea semilunaris*, which may be exactly defined by putting the muscle into action. It corresponds with a curved line, with its convexity outward, drawn from the end of the cartilage of the ninth rib to the spine of the os pubis, so that the centre of the line, at or near the umbilicus, is three inches from the median line. The

inner border of the Rectus corresponds to the *linea alba*, marked on the surface of the body by a groove, the *abdominal furrow*, which extends from the infrasternal fossa to, or to a little below, the umbilicus, where it gradually becomes lost. The surface of the Rectus presents three transverse furrows, the *lineæ transversæ*. The upper two of these, one opposite or a little below the tip of the ensiform cartilage, and another, midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. The umbilicus, situated in the *linea alba*, varies very much in position as regards its height. It is always situated above a zone drawn round the body opposite the highest point of the crest of the ilium, generally being about three-quarters of an inch to an inch above this line. It generally corresponds, therefore, to the fibro-cartilage between the third and fourth lumbar vertebræ.

2. Deep Muscles of the Abdomen.

Psoas magnus.
Psoas parvus.

Iliacus.
Quadratus lumborum.

The Psoas magnus, the Psoas parvus, and the Iliacus muscles, with the fascia covering them, will be described with the Muscles of the Lower Extremity.

The Fascia covering the Quadratus Lumborum.—This is the most anterior of the three layers of the lumbar fascia. It is a thin layer of fascia, which, passing over the anterior surface of the Quadratus lumborum, is attached, internally, to the bases of the transverse processes of the lumbar vertebræ; below, to the ilio-lumbar ligament; and above, to the apex and lower border of the last rib.

The portion of this fascia which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib constitutes the *ligamentum arcuatum externum*.

The *Quadratus lumborum* (Fig. 214, page 344) is situated in the lumbar region. It is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the ilio-lumbar ligament and the adjacent portion of the crest of the ilium for about two inches, and is inserted into the lower border of the last rib for about half its length, and by four small tendons, into the apices of the transverse processes of the four upper lumbar vertebræ. Occasionally a second portion of this muscle is found situated in front of the preceding. This arises from the upper borders of the transverse processes of three or four of the lower lumbar vertebræ, and is inserted into the lower margin of the last rib. The *Quadratus lumborum* is contained in a sheath formed by the anterior and middle lamellæ of the lumbar fasciæ.

Relations.—Its *anterior surface* (or rather the fascia which covers its anterior surface) is in relation with the colon, the kidney, the Psoas muscle, and the Diaphragm. Between the fascia and the muscle are the last dorsal, ilio-hypogastric, and ilio-inguinal nerves. Its *posterior surface* is in relation with the middle lamella of the lumbar fascia, which separates it from the Erector spinæ. The *Quadratus lumborum* extends, however, beyond the outer border of the Erector spinæ.

Nerve-supply.—The anterior branches of the last dorsal and first lumbar nerves; sometimes also a branch from the second lumbar nerve.

Actions.—The *Quadratus lumborum* draws down the last rib, and acts as a muscle of inspiration by helping to fix the origin of the Diaphragm. If the thorax and spine are fixed, it may act upon the pelvis, raising it toward its own side when only one muscle is put in action; and when both muscles act together, either from below or above, they flex the trunk.

IV. MUSCLES OF THE PELVIC OUTLET.

The muscles of this region are situated at the pelvic outlet in the ischio-rectal region and the perinæum. They include the following:

I. Muscles of the ischio-rectal region.

II. Muscles of the perinæum: A. In the Male; B. In the Female.

I. Muscles of the Ischio-rectal Region.

Corrugator cutis ani.
External sphincter ani.

Internal sphincter ani.
Levator ani.

Coccygeus.

The Corrugator Cutis Ani.—Around the anus is a thin stratum of involuntary muscular fibre, which radiates from the orifice. Internally, the fibres fade off into the submucous tissue, while externally they blend with the true skin. By its contraction it raises the skin into ridges around the margin of the anus.

The **External sphincter ani** is a thin, flat plane of muscular fibres, elliptical in shape and intimately adherent to the integument surrounding the margin of the anus. It measures about three or four inches in length from its anterior to its posterior extremity, being about an inch in breadth opposite the anus. It arises from the tip and back of the coccyx by a narrow tendinous band, and from the superficial fascia in front of that bone; and is inserted into the central tendinous point of the perinæum, joining with the Transversus perinæi, the Levator ani, and the Accelerator urinæ. Like other sphincter muscles, it consists of two planes of muscular fibre, which surround the margin of the anus and join in a commissure in front and behind, some fibres crossing from side to side in front and behind the anus.

FIG. 222.—Side view of pelvis, showing Levator ani. (From a preparation in the Museum of the Royal College of Surgeons.)

Nerve-supply.—A branch from the anterior division of the fourth sacral and the inferior hæmorrhoidal branch of the internal pudic.

Actions.—The action of this muscle is peculiar: 1. It is, like other muscles, always in a state of tonic contraction, and having no antagonistic muscle, it keeps the anal orifice closed. 2. It can be put into a condition of greater contraction under the influence of the will, so as to occlude more firmly the anal aperture in expiratory efforts unconnected with defecation. 3. Taking its fixed point at the coccyx, it helps to fix the central point of the perinæum, so that the Accelerator urinæ may act from this fixed point.

The **Internal sphincter ani** is a muscular ring which surrounds the lower

extremity of the rectum for about an inch, its inferior border being contiguous to, but quite separate from, the External sphincter. This muscle is about two lines in thickness, and is formed by an aggregation of the involuntary circular fibres of the intestine. It is paler in color and less coarse in texture than the External sphincter.

Actions.—Its action is entirely involuntary. It helps the External sphincter to occlude the anal aperture.

The **Levator ani** (Fig. 222) is a broad, thin muscle, situated on each side of the pelvis. It is attached to the inner surface of the sides of the true pelvis, and descending, unites with its fellow of the opposite side to form the floor of the pelvic cavity. It supports the viscera in this cavity and surrounds the various structures which pass through it. It arises, in front, from the posterior surface of the body of the os pubis on the outer side of the symphysis; posteriorly, from the inner surface of the spine of the ischium; and between these two points, from the angle of division between the obturator and recto-vesical layers of the pelvic fascia at their under part. The fibres pass downward to the middle line of the floor of the pelvis, and are inserted, the most posterior into the sides of the apex of the coccyx; those placed more anteriorly unite with the muscles of the opposite side in a median fibrous raphé, which extends between the coccyx and the margin of the anus. The middle fibres, which form the larger portion of the muscle, are inserted into the side of the rectum, blending with the fibres of the Sphincter muscles; lastly, the anterior fibres, the longest, descend upon the side of the prostate gland to unite beneath it with the muscle of the opposite side, blending with the fibres of the External sphincter and Transversus perinæi muscles at the central tendinous point of the perinæum.

The anterior portion is occasionally separated from the rest of the muscle by connective tissue. From this circumstance, as well as from its peculiar relation with the prostate gland, descending by its side, and surrounding it as in a sling, it has been described by Santorini and others as a distinct muscle, under the name of *Levator prostatae*. In the female, the anterior fibres of the *Levator ani* descend upon the side of the vagina.

Relations.—By its *inner* or *pelvic surface*, with the recto-vesical fascia, which separates it from the viscera of the pelvis and from the peritoneum. By its *outer* or *perineal surface*, it forms the inner boundary of the ischio-rectal fossa, and is covered by a thin layer of fascia, the *ischio-rectal* or *anal fascia*, given off from the obturator fascia. Its *posterior border* is free and separated from the Coccygeus muscle by a cellular interspace. Its *anterior border* is separated from the muscle of the opposite side by a triangular space, through which the urethra, and in the female the vagina, passes from the pelvis.

Nerve-supply.—A branch from the anterior division of the fourth sacral nerve and a branch from the pudic nerve, which is sometimes derived from the perineal, sometimes from the inferior hæmorrhoidal division.

Actions.—This muscle supports the lower end of the rectum and vagina, and also the bladder during the efforts of expulsion. It elevates and inverts the lower end of the rectum after it has been protruded and everted during the expulsion of the fæces. It is also a muscle of forced expiration.

The **Coccygeus** is situated behind and parallel with the preceding. It is a triangular plane of muscular and tendinous fibres, arising, by its apex, from the spine of the ischium and lesser sacro-sciatic ligament, and inserted, by its base, into the margin of the coccyx and into the side of the lower piece of the sacrum. It assists the *Levator ani* and *Pyriformis* in closing in the back part of the outlet of the pelvis.

Relations.—By its *inner* or *pelvic surface*, with the rectum. By its *external surface*, with the lesser sacro-sciatic ligament. The *lower border* is in relation with the posterior border of the *Levator ani*, but separated from it by a cellular interval: its *upper border* is in relation with the lower border of the *Pyriformis*, but separated from it by the sciatic and internal pudic vessels and nerve.

Nerve-supply.—A branch from the fourth and fifth sacral nerves.

Action.—The Coccygei muscles raise and support the coccyx, after it has been pressed backward during defecation or parturition.

II. A. Muscles and Fasciæ of the Perinæum in the Male.

Transversus perinæi.

Erector penis.

Accelerator urinæ.

Compressor urethræ.

Superficial Fascia.—The superficial fascia of the perinæum consists of two layers, superficial and deep, as in other regions of the body.

The *superficial layer* is thick, loose, areolar in texture, and contains much adipose tissue in its meshes, the amount of which varies in different subjects. In front, it is continuous with the dartos of the scrotum; behind, it is continuous with the subcutaneous areolar tissue surrounding the anus; and, on either side, with the same fascia on the inner side of the thighs. This layer should be carefully removed after it has been examined, when the deep layer will be exposed.

The *deep layer of superficial fascia* (Fascia of Colles) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos of the scrotum; on either side it is firmly attached to the margins of the rami of the os pubis and ischium, external to the crus penis, and as far back as the tuberosity of the ischium; posteriorly, it curves down behind the Transversus perinæi muscles to join

FIG. 223.—The perinæum. The integument and superficial layer of superficial fascia reflected.

the lower margin of the triangular ligament. This fascia not only covers the muscles in this region, but sends upward a vertical septum from its deep surface, which separates the back part of the subjacent space into two, the septum being incomplete in front.

The Central Tendinous Point of the Perinæum.—This is a fibrous point in the middle line of the perinæum, between the urethra and the rectum, being about half an inch in front of the anus. At this point four muscles converge and are attached: viz., the External sphincter ani, the Accelerator urinæ, and the two

Transversus perinæi; so that by the contraction of these muscles, which extend in opposite directions, it serves as a fixed point of support.

The **Transversus perinæi** is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inward, is inserted into the central tendinous point of the perinæum, joining in this situation

FIG. 224.—The muscles attached to the front of the pelvis. (From a preparation in the Museum of the Royal College of Surgeons of England.)

with the muscle of the opposite side, the External sphincter ani behind, and the Accelerator urinæ in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perinæum.

The **Accelerator urinæ** (*Ejaculator seminis*, or *Bulbo-cavernosus*) is placed in the middle line of the perinæum, immediately in front of the anus. It consists of two symmetrical halves, united along the median line by a tendinous raphé. It arises from the central tendon of the perinæum, and from the median raphé in front. From this point its fibres diverge like the plumes of a pen; the most

posterior form a thin layer, which is lost on the anterior surface of the triangular ligament; the middle fibres encircle the bulb and adjacent parts of the corpus spongiosum, and join with the fibres of the opposite side, on the upper part of the corpus spongiosum, in a strong aponeurosis; the anterior fibres, the longest and most distinct, spread out over the sides of the corpus cavernosum, to be inserted partly into that body, anterior to the Erector penis, occasionally extending to the os pubis; partly terminating in a tendinous expansion, which covers the dorsal vessels of the penis. The latter fibres are best seen by dividing the muscle longitudinally, and dissecting it outward from the surface of the urethra.

Action.—This muscle serves to empty the canal of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and it only comes into action at the end of the process. The middle fibres are supposed, by Krause, to assist in the erection of the corpus

FIG. 225.—The superficial muscles and vessels of the perineum.

spongiosum, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis, as they are inserted into, and continuous with, the fascia of the penis, compressing the dorsal vein during the contraction of the muscle.

The **Erector penis** (*Ischio-cavernous*) covers part of the crus penis. It is an elongated muscle, broader in the middle than at either extremity, and situated on either side of the lateral boundary of the perineum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis, from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It compresses the crus penis and retards the return of the blood through the veins, and thus serves to maintain the organ erect.

Between the muscles just examined a triangular space exists, bounded internally by the Accelerator urinæ, externally by the Erector penis, and behind

by the *Transversus perinæi*. The floor of this space is formed by the triangular ligament of the urethra (deep perineal fascia), and running from behind forward in it are the superficial perineal vessels and nerves, the long pudendal nerve; the transverse perineal artery coursing along the posterior boundary of the space on the *Transversus perinæi* muscle.

The **Triangular Ligament** (*Deep perineal fascia*) is stretched almost horizontally across the pubic arch, so as to close in the front part of the outlet of the pelvis. It consists of two dense membranous laminæ, which are united along their posterior borders, but are separated in front by intervening structures. The superficial of these two layers, the *inferior layer of the triangular ligament*, is triangular in shape, about an inch and a half in depth. Its apex is directed forward, and is separated from the subpubic ligament by an oval opening for the transmission of the dorsal vein of the penis. Its lateral margins are attached on each side to the rami of the ischium and os pubis, above the crura penis. Its base is directed toward the rectum, and connected to the central tendinous point of the perinæum. It is continuous with the deep layer of the superficial fascia behind the *Transversus perinæi* muscle, and with a thin fascia which covers the cutaneous surface of the *Levator ani* muscle (*anal or ischio-rectal fascia*).

FIG. 226.—Triangular ligament or deep perineal fascia. On the left side the superficial layer has been removed.

This layer of the triangular ligament is perforated, about an inch below the symphysis pubis, by the urethra, the aperture for which is circular in form and about three or four lines in diameter; by the arteries to the bulb and the ducts of Cowper's glands close to the urethral orifice; by the arteries to the corpora cavernosa—one on each side, close to the pubic arch and about halfway along the attached margin of the ligament; by the dorsal arteries and nerves of the penis near the apex of the ligament. Its base is also perforated by the superficial perineal vessels and nerves, while between its apex and the subpubic ligament the dorsal vein of the penis passes upward into the pelvis.

If this superficial or inferior layer of the triangular ligament is detached on either side, the following structures will be seen between it and the deeper layer: the dorsal vein of the penis; the membranous portion of the urethra, and the

Compressor urethræ muscle; Cowper's glands and their ducts; the pudic vessels and dorsal nerve of the penis; the artery and nerve of the bulb, and a plexus of veins.

The deep layer of the ligament (*superior layer of the triangular ligament*) is derived from the obturator fascia and stretches across the pubic arch. If the obturator fascia is traced inward after covering the Obturator internus muscle, it will be found to be attached by some of its deeper or anterior fibres to the inner margin of the ischio-pubic ramus, while its superficial or posterior fibres pass over this attachment to become the superior layer of the triangular ligament. Behind, this layer of the fascia is continuous with the inferior layer and with the fascia of Colles, and in front it is separated from the apex of the prostate gland through the intervention of a prolongation of the recto-vesical fascia. It is pierced by the urethra, or rather consists of two halves which are separated in the middle line by the urethra passing between them.

FIG. 227.—Muscles of the female perinæum.

The **Compressor urethræ** (*Constrictor urethræ*) surrounds the whole length of the membranous portion of the urethra, and is contained between the two layers of the triangular ligament. It arises, by aponeurotic fibres, from the junction of the rami of the os pubis and ischium, to the extent of half or three-quarters of an inch: each segment of the muscle passes inward, and divides into two fasciculi, which surround the urethra from the prostate gland behind to the bulbous portion of the urethra in front; and unite, at the upper and lower surfaces of this tube, with the muscle of the opposite side by means of a tendinous raphé.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During the transmission of fluids they, like the Acceleratores urinæ, are relaxed, and come into action only at the end of the process, to eject the last drops of the fluid.

II. B. Muscles of the Perinæum in the Female (Fig. 227).

Transversus perinæi.
Sphincter vaginæ.

Erector clitoridis.
Compressor urethræ.

The **Transversus perinæi** in the female is a narrow muscular slip, which passes more or less transversely across the back part of the perineal space. It arises by a small tendon from the inner and fore part of the tuberosity of the ischium, and, passing inward, is inserted into the central point of the perinæum, joining in this situation with the muscle of the opposite side, the **External sphincter ani** behind, and the **Sphincter vaginæ** in front.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—By their contraction they serve to fix the central tendinous point of the perinæum.

The **Sphincter vaginæ** surrounds the orifice of the vagina, and is analogous to the **Accelerator urinæ** in the male. It is attached posteriorly to the central tendinous point of the perinæum, where it blends with the **External sphincter ani**. Its fibres pass forward on each side of the vagina, to be inserted into the corpora cavernosa of the clitoris, a fasciculus crossing over the body of the organ so as to compress the dorsal vein.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris, as they are inserted into and are continuous with the fascia of the clitoris; compressing the dorsal vein during the contraction of the muscle.

The **Erector clitoridis** resembles the **Erector penis** in the male, but is smaller than it. It covers the unattached part of the crus clitoridis. It is an elongated muscle, broader at the middle than at either extremity, and situated on either side of the lateral boundary of the perinæum. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis from the surface of the crus, and from the adjacent portion of the ramus of the ischium. From these points fleshy fibres succeed, which end in an aponeurosis, which is inserted into the sides and under surface of the crus clitoridis.

Nerve-supply.—The perineal branch of the internal pudic.

Actions.—It compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the organ erect.

The **triangular ligament** (*deep perineal fascia*) in the female is not so strong as in the male. It is attached to the pubic arch, its apex being connected with the subpubic ligament. It is divided in the middle line by the aperture of the vagina, with the external coat of which it becomes blended, and in front of this is perforated by the urethra. Its posterior border is continuous, as in the male, with the deep layer of the superficial fascia around the **Transversus perinæi** muscle.

Like the triangular ligament in the male, it consists of two layers, between which are to be found the following structures: the dorsal vein of the clitoris, a portion of the urethra and the **Compressor urethræ** muscle, the glands of Bartholin and their ducts; the pudic vessels and the dorsal nerve of the clitoris; the arteries of the bulbi vestibuli, and a plexus of veins.

The **Compressor urethræ** (*Constrictor urethræ*) arises on each side from the margin of the descending ramus of the os pubis. The fibres, passing inward, divide into two sets: those of the fore part of the muscle are directed across the subpubic arch in front of the urethra to blend with the muscular fibres of the opposite side; while those of the hinder and larger part pass inward to blend with the wall of the vagina behind the urethra.

Nerve-supply.—The perineal branch of the internal pudic.

MUSCLES AND FASCIÆ OF THE UPPER EXTREMITY.

The Muscles of the Upper Extremity are divisible into groups, corresponding with the different regions of the limb.

I. OF THE THORACIC REGION.

1. *Anterior Thoracic Region.*

Pectoralis major. Pectoralis minor.
Subclavius.

2. *Lateral Thoracic Region.*

Lumbricales.
Interossei palmares.
Interossei dorsales.

Dissection of Pectoral Region and Axilla (Fig. 228).—The arm being drawn away from the side nearly at right angles with the trunk and rotated outward, make a vertical incision through the integument in the median line of the chest, from the upper to the lower part of the sternum; a second incision along the lower border of the Pectoral muscle, from the ensiform cartilage to the inner side of the axilla; a third, from the sternum along the clavicle, as far as its centre; and a fourth, from the middle of the clavicle obliquely downward, along the interspace between the Pectoral and Deltoid muscles, as low as the fold of the armpit. The flap of integument is then to be dissected off in the direction indicated in the figure, but not entirely removed, as it should be replaced on completing the dissection. If a transverse incision is now made from the lower end of the sternum to the side of the chest, as far as the posterior fold of the armpit, and the integument reflected outward, the axillary space will be more completely exposed.

I. Muscles and Fasciæ of the Thoracic Region.

1. Anterior Thoracic Region.

Pectoralis major.

Pectoralis minor.

Subclavius.

The superficial fascia of the thoracic region is a loose cellulo-fibrous layer enclosing masses of fat in its spaces. It is continuous with the superficial fascia of the neck and upper extremity above, and of the abdomen below. Opposite the mamma it divides into two layers, one of which passes in front, the other behind, that gland; and from both of these layers numerous septa pass into its substance, supporting its various lobes: from the anterior layer fibrous processes pass forward to the integument and nipple. These processes were called by Sir A. Cooper the *ligamenta suspensoria*, from the support they afford to the gland in this situation.

The deep fascia of the thoracic region is a thin aponeurotic lamina, covering the surface of the great Pectoral muscle, and sending numerous prolongations

FIG. 228.—Dissection of upper extremity.

between its fasciculi: it is attached, in the middle line, to the front of the sternum, and above to the clavicle; externally and below it becomes continuous with the fascia over the shoulder, axilla, and thorax. It is very thin over the upper part of the muscle, thicker in the interval between the Pectoralis major and Latissimus dorsi, where it closes in the axillary space, and divides at the outer margin of the latter muscle into two layers, one of which passes in front and the other behind it; these proceed as far as the spinous processes of the dorsal vertebræ, to which they are attached. As the fascia leaves the lower edge of the Pectoralis major to pass across the floor of the axilla it sends a layer upward under cover of the muscle: this lamina splits to envelop the Pectoralis minor, at the upper edge of which it becomes continuous with the costo-coracoid membrane. The hollow of the armpit, seen when the arm is abducted, is mainly produced by the traction of this

fascia on the axillary floor, and hence it is sometimes named the *suspensory ligament* of the axilla. At the lower part of the thoracic region this fascia is well developed, and is continuous with the fibrous sheath of the Recti muscles.

The **Pectoralis major** (Fig. 229) is a broad, thick, triangular muscle, situated at the upper and fore part of the chest, in front of the axilla. It arises from the anterior surface of the sternal half of the clavicle; from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib; this portion of its origin consists of aponeurotic fibres, which intersect with those of the opposite muscle; it also arises from the cartilages of all the true ribs, with the exception, frequently, of the first or of the seventh, or both; and from the aponeurosis of the External oblique muscle of the abdomen. The fibres from this extensive origin converge toward its insertion, giving to the muscle a radiated appearance. Those fibres which arise from the clavicle pass obliquely outward and downward, and are usually separated from the rest by a cellular interval: those from the lower part of the sternum, and the cartilages of the lower true ribs, pass upward and outward, whilst the middle fibres pass horizontally. They all terminate in a flat tendon, about two inches broad, which is inserted into the outer bicipital ridge of the humerus. This tendon consists of two laminæ, placed one in front of the other, and usually blended together below. The anterior, the thicker, receives the clavicular and upper half of the sternal portion of the muscle; and its fibres are inserted in the same order as that in which they arise; that is to say, the outermost fibres of origin from the clavicle are inserted at the uppermost part of the tendon; the upper fibres of origin from the sternum pass down to the lowermost part of this anterior lamina of the tendon and extend as low as the tendon of the Deltoid and join with it. The posterior lamina of the tendon receives the attachment of the lower half of the sternal portion and the deeper part of the muscle from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, ascend the higher, turning backward successively behind the superficial and upper ones, so that the tendon appears to be twisted. The posterior lamina reaches higher on the humerus than the anterior one, and from it an expansion is given off which covers the bicipital groove and blends with the capsule of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the bicipital groove of the humerus, while from the lower border of the tendon a third expansion passes downward to the fascia of the arm.

Relations.—By its *anterior surface*, with the integument, the superficial fascia, the Platysma, some of the branches of the descending cervical nerves, the mammary gland, and the deep fascia; by its *posterior surface*: its *thoracic portion*, with the sternum, the ribs and costal cartilages, the costo-coracoid membrane, the Subclavius, Pectoralis minor, Serratus magnus, and the Intercostals; its *axillary portion* forms the anterior wall of the axillary space, and covers the axillary vessels and nerves, the Biceps and Coraco-brachialis muscles. Its *upper border* lies parallel with the Deltoid, from which it is separated by a slight interspace in which lie the cephalic vein and humeral branch of the acromial thoracic artery. Its *lower border* forms the anterior margin of the axilla, being at first separated from the Latissimus dorsi by a considerable interval; but both muscles gradually converge toward the outer part of the space.

Dissection.—Detach the Pectoralis major by dividing the muscle along its attachment to the clavicle, and by making a vertical incision through its substance a little external to its line of attachment to the sternum and costal cartilages. The muscle should then be reflected outward, and its tendon carefully examined. The Pectoralis minor is now exposed, and immediately above it, in the interval between its upper border and the clavicle, a strong fascia, the *costo-coracoid membrane*.

The **costo-coracoid membrane** is a strong fascia, situated under cover of the clavicular portion of the Pectoralis major muscle. It occupies the interval between the Pectoralis minor and Subclavius muscles, and protects the axillary vessels and

nerves. Traced upward, it splits to enclose the Subclavius muscle, and its two layers are attached to the clavicle, one in front of and the other behind the muscle; the latter layer fuses with the deep cervical fascia and with the sheath of the axillary vessels. Internally, it blends with the fascia covering the first two inter-

FIG. 229.—Muscles of the chest and front of the arm. Superficial view.

costal spaces, and is attached also to the first rib internal to the origin of the Subclavius muscle. Externally it is very thick and dense, and is attached to the coracoid process. The portion extending from its attachment to the first rib to the coracoid process is often whiter and denser than the rest; this is sometimes called the *costo-coracoid ligament*. Below, it is thin, and at the upper border of the Pectoralis minor it splits into two layers to invest the muscle; from the lower border of the Pectoralis minor it is continued downward to join the axillary fascia, and outward to join the fascia over the short head of the Biceps. The costo-coracoid membrane is pierced by the cephalic vein, the acromial thoracic artery and vein, superior thoracic artery, and anterior thoracic nerves.

The **Pectoralis minor** (Fig. 230) is a thin, flat, triangular muscle, situated at the upper part of the thorax, beneath the Pectoralis major. It arises by three

tendinous digitations from the upper margin and outer surface of the third, fourth, and fifth ribs, near their cartilages, and from the aponeurosis covering the Inter-costal muscles; the fibres pass upward and outward, and converge to form a flat tendon, which is inserted into the inner border and upper surface of the coracoid process of the scapula.

Relations.—By its *anterior surface*, with the Pectoralis major and the thoracic

FIG. 230.—Muscles of the chest and front of the arm, with the boundaries of the axilla.

branches of the acromial thoracic artery. By its *posterior surface*, with the ribs, Intercostal muscles, Serratus magnus, the axillary space, and the axillary vessels and brachial plexus of nerves. Its upper border is separated from the clavicle by a triangular interval, broad internally, narrow externally, which is occupied by the costo-coracoid membrane. In this space is the first part of the axillary vessels and nerves. Running parallel to the lower border of the muscle is the long thoracic artery.

The costo-coracoid membrane should now be removed, when the Subclavius muscle will be seen.

The **Subclavius** is a small triangular muscle, placed in the interval between the clavicle and the first rib. It arises by a short, thick tendon from the first rib and its cartilage at their junction, in front of the rhomboid ligament; the fleshy fibres proceed obliquely upward and outward, to be inserted into a deep groove on the under surface of the clavicle.

Relations.—By its *upper surface*, with the clavicle. By its *deep surface* it is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the costo-coracoid

membrane, which, with the clavicle, forms an osseo-fibrous sheath in which the muscle is enclosed.

If the costal attachment of the Pectoralis minor is divided across, and the muscle reflected outward, the axillary vessels and nerves are brought fully into view, and should be examined.

Nerves.—The Pectoral muscles are supplied by the anterior thoracic nerves; the Pectoralis major through these nerves receives filaments from all the spinal nerves entering into the formation of the brachial plexus; the Pectoralis minor receives its fibres from the eighth cervical and first dorsal nerves. The Subclavius is supplied by a filament from the fifth cervical nerve.

Actions.—If the arm has been raised by the Deltoid, the Pectoralis major will, conjointly with the Latissimus dorsi and Teres major, depress it to the side of the chest. If acting alone, it adducts and draws forward the arm, bringing it across the front of the chest, and at the same time rotates it inward. The Pectoralis minor depresses the point of the shoulder, drawing the scapula downward and inward to the thorax, and throwing the inferior angle backward. The Subclavius depresses the shoulder, drawing the clavicle downward and forward. When the arms are fixed, all three muscles act upon the ribs, drawing them upward and expanding the chest, and thus becoming very important agents in forced inspiration. Asthmatic patients always assume an attitude which fixes the shoulders, so that all these muscles may be brought into action to assist in dilating the cavity of the chest.

2. Lateral Thoracic Region.

Serratus magnus.

The **Serratus magnus** (Fig. 231) is a thin, irregularly quadrilateral muscle, situated between the ribs and the scapula at the upper and lateral part of the chest. It arises by nine digitations or slips from the outer surface and upper border of the eight upper ribs (the second rib giving origin to two slips), and from the aponeurosis covering the corresponding intercostal muscles. From this extensive attachment the fibres pass backward, closely applied to the chest-wall, and reach the vertebral border of the scapula, and are inserted into its ventral aspect in the following manner. The upper two digitations—i. e., the one from the first rib and the higher, of the two from the second rib—converge to be inserted into a triangular area on the ventral aspect of the superior angle. The next two digitations spread out to form a thin triangular sheet, the base of which is directed backward and is inserted into nearly the whole length of the ventral aspect of the vertebral border. The lower five digitations converge, as they pass backward from the ribs, to form a fan-shaped structure, the apex of which is inserted, partly by muscular and partly by tendinous fibres, into a triangular impression on the ventral aspect of the inferior angle. The lower four slips interdigitate at their origin with the upper five slips of the **External oblique** muscle of the abdomen.

FIG. 231.—Serratus magnus. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Relations.—This muscle is partly covered, in front, by the Pectoral muscles; behind, by the Subscapularis. The axillary vessels and nerves lie upon its upper part, while its *deep surface* rests upon the ribs and intercostal muscles.

Nerve.—The Serratus magnus is supplied by the posterior thoracic nerve, which is derived from the fifth, sixth, and generally the seventh cervical nerves.

Actions.—The Serratus magnus, as a whole, carries the scapula forward, and at the same time raises the vertebral border of the bone. It is therefore concerned in the action of pushing. Its lower and stronger fibres move forward the lower angle and assist the Trapezius in rotating the bone round an axis through its centre, and thus assists this muscle in raising the acromion and supporting weights upon the shoulder. It is also an assistant to the Deltoid in raising the arm, inasmuch as during the action of this latter muscle it fixes the scapula and so steadies the glenoid cavity on which the head of the humerus rotates. After the Deltoid has raised the arm to a right angle with the trunk, the Serratus magnus and the Trapezius, by rotating the scapula, raise the arm into an almost vertical position. It is possible that when the shoulders are fixed the lower fibres of the Serratus magnus may assist in raising and everting the ribs; but it is not the important inspiratory muscle which it was formerly believed to be.

Surgical Anatomy.—When the muscle is paralyzed, the vertebral border, and especially the lower angle of the scapula, leaves the ribs and stands out prominently on the surface, giving a peculiar “winged” appearance to the back. The patient is unable to raise the arm, and an attempt to do so is followed by a further projection of the lower angle of the scapula from the back of the thorax.

Dissection.—After completing the dissection of the axilla, if the muscles of the back have been dissected, the upper extremity should be separated from the trunk. Saw through the clavicle at its centre, and then cut through the muscles which connect the scapula and arm with the trunk, viz.: the Pectoralis minor in front, Serratus magnus at the side, and the Levator anguli scapulæ, the Rhomboids, Trapezius, and Latissimus dorsi behind. These muscles should be cleaned and traced to their respective insertions. Then make an incision through the integument, commencing at the outer third of the clavicle, and extending along the margin of that bone, the acromion process, and spine of the scapula; the integument should be dissected from above downward and outward, when the fascia covering the Deltoid is exposed (Fig. 228, No. 3).

II. MUSCLES AND FASCIÆ OF THE SHOULDER AND ARM

The superficial fascia of the upper extremity is a thin cellulo-fibrous layer, containing the superficial veins and lymphatics, and the cutaneous nerves. It is most distinct in front of the elbow, and contains very large superficial veins and nerves; in the hand it is hardly demonstrable, the integument being closely adherent to the deep fascia by dense fibrous bands. Small subcutaneous bursæ are found in this fascia over the acromion, the olecranon, and the knuckles. The deep fascia of the upper extremity comprises the aponeurosis of the shoulder, arm, and forearm, the anterior and posterior annular ligaments of the carpus, and the palmar fascia. These will be considered in the description of the muscles of the several regions.

3. Acromial Region.

Deltoid.

The deep fascia covering the Deltoid (deltoid aponeurosis) is a fibrous layer which covers the outer surface of the muscle, thick and strong behind, where it is continuous with the infraspinatus fascia, thinner over the rest of its extent. It sends down numerous prolongations between the fasciculi of the muscle. In front, it is continuous with the fascia covering the great Pectoral muscle; behind, with that covering the Infraspinatus; above, it is attached to the clavicle, the acromion, and spine of the scapula; below, it is continuous with the deep fascia of the arm.

The Deltoid (Fig. 229) is a large, thick, triangular muscle, which gives the rounded outline to the shoulder, and has received its name from its resemblance to the Greek letter Δ reversed. It surrounds the shoulder-joint in the greater part of its extent, covering it on its outer side, and in front and behind. It arises from

the outer third of the anterior border and upper surface of the clavicle; from the outer margin and upper surface of the acromion process, and from the lower lip of the posterior border of the spine of the scapula, as far back as the triangular surface at its inner end. From this extensive origin the fibres converge toward their insertion, the middle passing vertically, the anterior obliquely, backward, the posterior obliquely forward; they unite to form a thick tendon, which is inserted into a rough triangular prominence on the middle of the outer side of the shaft of the humerus. At its insertion the muscle gives off an expansion to the deep fascia of the arm. This muscle is remarkably coarse in texture, and the arrangement of its muscular fibres is somewhat peculiar; the central portion of the muscle—that is to say, the part arising from the acromion process—consists of oblique fibres, which arise in a bipenniform manner from the sides of tendinous intersections, generally four in number, which are attached above to the acromion process and pass downward parallel to one another in the substance of the muscle. The oblique muscular fibres thus formed are inserted into similar tendinous intersections, generally three in number, which pass upward from the insertion of the muscle into the humerus and alternate with the descending septa. The portions of the muscle which arise from the clavicle and spine of the scapula are not arranged in this manner, but pass from their origin above, to be inserted into the margins of the inferior tendon.

Relations.—By its *superficial surface*, with the integument, the superficial and deep fasciæ, Platysma, and supra-acromial nerves. Its *deep surface* is separated from the head of the humerus by a large sacculated synovial bursa, and covers the coracoid process, coraco-acromial ligament, Pectoralis minor, Coraco-brachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Supraspinatus, Infraspinatus, and Teres minor, the scapular and external heads of the Triceps, the circumflex vessels and nerve, and the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by a cellular interspace, which lodges the cephalic vein and humeral branch of the acromial thoracic artery: lower down the two muscles are in close contact. Its *posterior border* rests on the Infraspinatus and Triceps muscles.

Nerves.—The Deltoid is supplied by the fifth and sixth cervical through the circumflex nerve.

Actions.—The Deltoid raises the arm directly from the side, so as to bring it at right angles with the trunk. Its anterior fibres, assisted by the Pectoralis major, draw the arm forward; and its posterior fibres, aided by the Teres major and Latissimus dorsi, draw it backward.

Surgical Anatomy.—The Deltoid is very liable to atrophy, and when in this condition simulates dislocation of the shoulder-joint, as there is flattening of the shoulder and apparent prominence of the acromion process; upon examination, however, it will be found that the relative position of the great tuberosity of the humerus to the acromion and coracoid process is unchanged. Atrophy of the Deltoid may be due to disuse or loss of trophic influence, either from injury to the circumflex nerve or cord lesions, as in infantile paralysis.

Dissection.—Divide the Deltoid across, near its upper part, by an incision carried along the margin of the clavicle, the acromion process and spine of the scapula, and reflect it downward, when the structures under cover of it will be seen.

4. Anterior Scapular Region.

Subscapularis.

The **subscapular fascia** is a thin membrane attached to the entire circumference of the subscapular fossa, and affording attachment by its inner surface to some of the fibres of the Subscapularis muscle: when this is removed, the Subscapularis muscle is exposed.

The **Subscapularis** (Fig. 230) is a large triangular muscle which fills up the subscapular fossa, arising from its internal two-thirds, with the exception of a narrow margin along the posterior border, and the surfaces at the superior and inferior angles which afford attachment to the Serratus magnus: it also arises from

the lower two-thirds of the groove on the axillary border of the bone. Some fibres arise from tendinous laminæ, which intersect the muscle, and are attached to ridges on the bone; and others from an aponeurosis, which separates the muscle from the Teres major and the long head of the Triceps. The fibres pass outward, and, gradually converging, terminate in a tendon, which is inserted into the lesser tuberosity of the humerus. Those fibres which arise from the axillary border of the scapula are inserted into the neck of the humerus to the extent of an inch below the tuberosity. The tendon of the muscle is in close contact with the anterior part of the capsular ligament of the shoulder-joint, and glides over a large bursa, which separates it from the base of the coracoid process. This bursa communicates with the cavity of the joint by an aperture in the capsular ligament.

Relations.—Its *anterior surface* forms a considerable part of the posterior wall of the axilla, and is in relation with the Serratus magnus, Coraco-brachialis, and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. By its *posterior surface*, with the scapula and the capsular ligament of the shoulder-joint. Its *lower border* is contiguous with the Teres major and Latissimus dorsi.

Nerves.—It is supplied by the fifth and sixth cervical nerves through the upper and lower subscapular nerves.

Actions.—The Subscapularis rotates the head of the humerus inward; when the arm is raised, it draws the humerus forward and downward. It is a powerful defence to the front of the shoulder-joint, preventing displacement of the head of the bone.

5. Posterior Scapular Region (Fig. 232).

Supraspinatus.
Infraspinatus.

Teres minor.
Teres major.

Dissection.—To expose these muscles, and to examine their mode of insertion into the humerus, detach the Deltoid and Trapezius from their attachment to the spine of the scapula and acromion process. Remove the clavicle by dividing the ligaments connecting it with the coracoid process, and separate it at its articulation with the scapula: divide the acromion process near its root with a saw. The fragments being removed, the tendons of the posterior Scapular muscles will be fully exposed, and can be examined. A block should be placed beneath the shoulder-joint, so as to make the muscles tense.

The **Supraspinous fascia** is a thick and dense membranous layer, which completes the osseo-fibrous case in which the Supraspinatus muscle is contained, affording attachment, by its inner surface, to some of the fibres of the muscle. It is thick internally, but thinner externally under the coraco-acromial ligament. When this fascia is removed, the Supraspinatus muscle is exposed.

The **Supraspinatus muscle** occupies the whole of the supraspinous fossa, arising from its internal two-thirds and from the strong fascia which covers its surface. The muscular fibres converge to a tendon which passes across the upper part of the capsular ligament of the shoulder-joint, to which it is intimately adherent, and is inserted into the highest of the three facets on the great tuberosity of the humerus.

Relations.—By its *upper surface*, with the Trapezius, the clavicle, the acromion, the coraco-acromial ligament, and the Deltoid; by its *under surface*, with the scapula, the suprascapular vessels and nerve, and upper part of the shoulder-joint.

The **Infraspinous fascia** is a dense fibrous membrane, covering in the Infraspinatus muscle and attached to the circumference of the infraspinous fossa; it affords attachment, by its inner surface, to some fibres of that muscle. At the point where the Infraspinatus commences to be covered by the Deltoid, this fascia divides into two layers: one layer passes over the Deltoid muscle, helping to form the Deltoid fascia already described; the other passes beneath the Deltoid to the shoulder-joint.

The **Infraspinatus** is a thick, triangular muscle, which occupies the chief part of the infraspinous fossa, arising by fleshy fibres from its internal two-thirds, and

by tendinous fibres from the ridges on its surface: it also arises from a strong fascia which covers it externally, and separates it from the Teres major and minor. The fibres converge to a tendon which glides over the external border of the spine of the scapula, and, passing across the posterior part of the capsular ligament of the shoulder-joint, is inserted into the middle facet on the great tuberosity of the humerus. The tendon of this muscle is occasionally separated from the spine of the scapula by a synovial bursa which communicates with the synovial cavity of the shoulder-joint.

Relations.—By its *posterior surface*, with the Deltoid, the Trapezius, Latissimus dorsi, and the integument; by its *anterior surface*, with the scapula, from which

FIG. 232.—Muscles on the dorsum of the Scapula and the Triceps.

it is separated by the suprascapular and dorsalis scapulæ vessels, and with the capsular ligament of the shoulder-joint. Its *lower border* is in contact with the Teres minor, occasionally united with it, and with the Teres major.

The **Teres minor** is a narrow, elongated muscle, which arises from the dorsal surface of the axillary border of the scapula for the upper two-thirds of its extent, and from two aponeurotic laminæ, one of which separates this muscle from the Infraspinatus, the other from the Teres major; its fibres pass obliquely upward and outward, and terminate in a tendon which is inserted into the lowest of the three facets on the great tuberosity of the humerus, and, by fleshy fibres, into the humerus immediately below it. The tendon of this muscle passes across the posterior part of the capsular ligament of the shoulder-joint.

Relations.—By its *posterior surface*, with the Deltoid and the integument; by its *anterior surface*, with the scapula and dorsal branch of the subscapular artery, the long head of the Triceps, and the shoulder-joint; by its *upper border*, with the Infraspinatus; by its *lower border*, with the Teres major, from which it is separated anteriorly by the long head of the Triceps.

The **Teres major** is a thick but somewhat flattened muscle, which arises from the oval surface on the dorsal aspect of the inferior angle of the scapula, and from the fibrous septa interposed between it and the **Teres minor** and **Infraspinatus**; the fibres are directed upward and outward, and terminate in a flat tendon, about two inches in length, which is inserted into the inner bicipital ridge of the humerus. The tendon of this muscle, at its insertion into the humerus, lies behind that of the **Latissimus dorsi**, from which it is separated by a synovial bursa, the two tendons being, however, united along their lower borders for a short distance.

Relations.—By its *posterior surface*, with the **Latissimus dorsi** below, and the long head of the **Triceps** above. By its *anterior surface*, with the **Subscapularis**, **Latissimus dorsi**, **Coraco-brachialis**, short head of the **Biceps**, the axillary vessels, and brachial plexus of nerves. Its *upper border* is at first in relation with the **Teres minor**, from which it is afterward separated by the long head of the **Triceps**. Its *lower border* forms, in conjunction with the **Latissimus dorsi**, part of the posterior boundary of the axilla. The **Latissimus dorsi** at first covers the origin of the **Teres major**, then wraps itself obliquely round its lower border, so that its tendon ultimately comes to lie in front of that of the **Teres major**.

Nerves.—The **Supra-** and **Infra-spinatus** muscles are supplied by the fifth and sixth cervical nerves through the suprascapular nerve; the **Teres minor**, by the fifth cervical, through the circumflex; and the **Teres major**, by the fifth and sixth cervical, through the lower subscapular.

Actions.—The **Supraspinatus** assists the **Deltoid** in raising the arm from the side, and fixes the head of the humerus in the glenoid cavity. The **Infraspinatus** and **Teres minor** rotate the head of the humerus outward: when the arm is raised, they assist in retaining it in that position and carrying it backward. One of the most important uses of these three muscles is the great protection they afford to the shoulder-joint, the **Supraspinatus** supporting it above, and preventing displacement of the head of the humerus upward, while the **Infraspinatus** and **Teres minor** protect it behind, and prevent dislocation backward. The **Teres major** assists the **Latissimus dorsi** in drawing the humerus downward and backward, when previously raised, and rotating it inward; when the arm is fixed, it may assist the **Pectoral** and **Latissimus dorsi** muscles in drawing the trunk forward.

THE ARM.

6. Anterior Humeral Region (Fig. 230).

Coraco-brachialis.

Biceps.

Brachialis anticus.

Dissection.—The arm being placed on the table, with the front surface uppermost, make a vertical incision through the integument along the middle line, from the outer extremity of the anterior fold of the axilla to about two inches below the elbow-joint, where it should be joined by a transverse incision, extending from the inner to the outer side of the forearm; the two flaps being reflected on either side, the fascia should be examined (Fig. 228).

The **deep fascia** of the arm is continuous with that covering the **Deltoid** and the great **Pectoral** muscles, by means of which it is attached, above, to the clavicle, acromion, and spine of the scapula; it forms a thin, loose, membranous sheath investing the muscles of the arm, sending down septa between them, and composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It differs in thickness at different parts, being thin over the **Biceps**, but thicker where it covers the **Triceps**, and over the condyles of the humerus; it is strengthened by fibrous aponeuroses, derived from the **Pectoralis major** and **Latissimus dorsi** on the inner side, and from the **Deltoid** externally. On either side it gives off a strong *intermuscular septum*, which is attached to the supracondylar ridge and condyle of the humerus. These septa serve to separate the muscles of the anterior from those of the posterior brachial region. The external intermuscular septum extends from the lower part of the anterior bicipital ridge, along the external supracondylar ridge, to the outer condyle; it is blended with the tendon of the **Deltoid**, gives attachment to the **Triceps** behind, to the **Brachialis anticus**, **Supinator longus**, and **Extensor carpi radialis longior**, in front, and is

perforated by the musculo-spiral nerve and superior profunda artery. The internal intermuscular septum, thicker than the preceding, extends from the lower part of the posterior lip of the bicipital groove below the Teres major, along the internal supra-condylar ridge to the inner condyle; it is blended with the tendon of the Coracobrachialis, and affords attachment to the Triceps behind, and the Brachialis anticus in front. It is perforated by the ulnar nerve and the inferior profunda and anastomotic arteries. At the elbow the deep fascia is attached to all the prominent points round the joint—viz. the condyles of the humerus and the olecranon process of the ulna—and is continuous with the deep fascia of the forearm. Just below the middle of the arm, on its inner side, in front of the internal intermuscular septum, is an oval opening in the deep fascia which transmits the basilic vein and some lymphatic vessels. On the removal of this fascia the muscles, vessels, and nerves of the anterior humeral region are exposed.

The *Coraco-brachialis*, the smallest of the three muscles in this region, is situated at the upper and inner part of the arm. It arises by fleshy fibres from the apex of the coracoid process, in common with the short head of the Biceps, and from the intermuscular septum between the two muscles; the fibres pass downward, backward, and a little outward, to be inserted by means of a flat tendon into an impression at the middle of the inner surface and internal border of the shaft of the humerus between the origins of the Triceps and Brachialis anticus. It is perforated by the musculo-cutaneous nerve. The inner border of the muscle forms a guide to the position of the brachial artery in tying the vessel in the upper part of its course.

Relations.—By its *anterior surface*, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve which cross it; by its *posterior surface*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the inner head of the Triceps, the humerus, and the anterior circumflex vessels; by its *inner border*, with the brachial artery, and the median and musculo-cutaneous nerves; by its *outer border*, with the short head of the Biceps and Brachialis anticus.

The *Biceps* (*Biceps flexor cubiti*) is a long fusiform muscle, occupying the whole of the anterior surface of the arm, and divided above into two portions or heads, from which circumstance it has received its name. The short head arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coracobrachialis. The long head arises from the upper margin of the glenoid cavity, and is continuous with the glenoid ligament. This tendon arches over the head of the humerus, being enclosed in a special sheath of the synovial membrane of the shoulder-joint; it then passes through an opening in the capsular ligament at its attachment to the humerus, and descends in the bicipital groove, in which it is retained by a fibrous prolongation from the tendon of the Pectoralis major. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can readily be separated until within about three inches of the elbow-joint. Here they end in a flattened tendon, which is inserted into the back part of the tuberosity of the radius, a synovial bursa being interposed between the tendon and the front of the tuberosity. As the tendon of the muscle approaches the radius it becomes twisted upon itself, so that its anterior surface becomes external and is applied to the tuberosity of the radius at its insertion: opposite the bend of the elbow the tendon gives off, from its inner side, a broad aponeurosis, the *bicipital fascia* (*semilunar fascia*), which passes obliquely downward and inward across the brachial artery, and is continuous with the deep fascia of the forearm (Fig. 229). The inner border of this muscle forms a guide to the position of the vessel in tying the brachial artery in the middle of the arm.¹

¹ A third head to the Biceps is occasionally found (Theile says as often as once in eight or nine subjects), arising at the upper and inner part of the Brachialis anticus, with the fibres of which it is continuous, and inserted into the bicipital fascia and inner side of the tendon of the Biceps. In most cases this additional slip passes behind the brachial artery in its course down the arm. Occasionally the third head consists of two slips which pass down, one in front, the other behind the artery, concealing the vessel in the lower half of the arm.

Relations.—Its *anterior surface* is overlapped above by the Pectoralis major and Deltoid; in the rest of its extent it is covered by the superficial and deep fasciæ and the integument. Its *posterior surface* rests above on the shoulder-joint and upper part of the humerus; below it rests on the Brachialis anticus, with the musculo-cutaneous nerve intervening between the two, and on the Supinator brevis. Its *inner border* is in relation with the Coraco-brachialis, and overlaps the brachial vessels and median nerve; its *outer border*, with the Deltoid and Supinator longus.

The **Brachialis anticus** is a broad muscle, which covers the elbow-joint and the lower half of the front of the humerus. It is somewhat compressed from before backward, and is broader in the middle than at either extremity. It arises from the lower half of the outer and inner surfaces of the shaft of the humerus, and commences above at the insertion of the Deltoid, which it embraces by two angular processes. Its origin extends below, to within an inch of the margin of the articular surface, and is limited on each side by the external and internal borders of the shaft of the humerus. It also arises from the intermuscular septa on each side, but more extensively from the inner than the outer, from which it is separated below by the Supinator longus and Extensor carpi radialis longior. Its fibres converge to a thick tendon, which is inserted into a rough depression on the anterior surface of the coronoid process of the ulna, being received into an interval between two fleshy slips of the Flexor profundus digitorum.

Relations.—By its *anterior surface*, with the Biceps, the brachial vessels, musculo-cutaneous, and median nerves; by its *posterior surface*, with the humerus and front of the elbow-joint; by its *inner border*, with the Triceps, ulnar nerve, and Pronator radii teres, from which it is separated by the intermuscular septum; by its *outer border*, with the musculo-spiral nerve, radial recurrent artery, the Supinator longus, and Extensor carpi radialis longior.

Nerves.—The muscles of this group are supplied by the musculo-cutaneous nerve. The Brachialis anticus usually receives an additional filament from the musculo-spiral. The Coraco-brachialis receives its supply primarily from the seventh cervical, the Biceps and Brachialis anticus from the fifth and sixth cervical nerves.

Actions.—The Coraco-brachialis draws the humerus forward and inward, and at the same time assists in elevating it toward the scapula. The Biceps is a flexor of the forearm; it is also a powerful supinator, and serves to render tense the deep fascia of the forearm by means of the broad aponeurosis given off from its tendon. The Brachialis anticus is a flexor of the forearm, and forms an important defence to the elbow-joint. When the forearm is fixed, the Biceps and Brachialis anticus flex the arm upon the forearm, as is seen in efforts of climbing.

7. Posterior Humeral Region.

Triceps.

Subanconeus.

The **Triceps** (*Triceps extensor cubiti*) (Fig. 232) is situated on the back of the arm, extending the entire length of the posterior surface of the humerus. It is of large size, and divided above into three parts; hence its name. These three portions have been named (1) the middle, scapular, or long head; (2) the external, or long humeral; and (3) the internal, or short humeral head.

The *middle* or *scapular head* arises, by a flattened tendon, from a rough triangular depression on the scapula, immediately below the glenoid cavity, being blended at its upper part with the capsular ligament; the muscular fibres pass downward between the two other portions of the muscle, and join with them in the common tendon of insertion.

The *external head* arises from the posterior surface of the shaft of the humerus, between the insertion of the Teres minor and the upper part of the musculo-spiral groove; from the external border of the humerus and the external intermuscular

septum: the fibres from this origin converge toward the common tendon of insertion.

The *internal head* arises from the posterior surface of the shaft of the humerus, below the groove for the musculo-spiral nerve; commencing above, narrow and pointed, below the insertion of the *Teres major*, and extending to within an inch of the trochlear surface: it also arises from the internal border of the humerus, and from the back of the whole length of the internal and lower part of the external intermuscular septa. The fibres of this portion of the muscle are directed, some downward to the olecranon, whilst others converge to the common tendon of insertion.

The *common tendon* of the *Triceps* commences about the middle of the back part of the muscle: it consists of two aponeurotic laminæ, one of which is subcutaneous and covers the posterior surface of the muscle for the lower half of its extent; the other is more deeply seated in the substance of the muscle: after receiving the attachment of the muscular fibres, they join together above the elbow, and are inserted, for the most part, into the back part of the upper surface of the olecranon process; a band of fibres is, however, continued downward, on the outer side, over the *Anconeus*, to blend with the deep fascia of the forearm. A small bursa, occasionally multilocular, is situated on the front part of this surface, beneath the tendon.

The long head of the *Triceps* descends between the *Teres minor* and *Teres major*, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (Fig. 232). The triangular space contains the *dorsalis scapulæ* vessels; it is bounded by the *Teres minor* above, the *Teres major* below, and the scapular head of the *Triceps* externally: the quadrangular space transmits the posterior circumflex vessels and the circumflex nerve; it is bounded by the *Teres minor* above, the *Teres major* below, the scapular head of the *Triceps* internally, and the humerus externally.

Relations.—By its *posterior surface*, with the *Deltoid* above: in the rest of its extent it is subcutaneous; by its *anterior surface*, with the humerus, musculo-spiral nerve, superior profunda vessels, and back part of the elbow-joint. Its *middle* or *long head* is in relation, behind, with the *Deltoid* and *Teres minor*; in front, with the *Subscapularis*, *Latissimus dorsi*, and *Teres major*.

The *Subanconeus* is a name given to a few fibres from the under surface of the lower part of the *Triceps* muscle, which are inserted into the posterior ligament of the elbow-joint. By some authors it is regarded as the analogue of the *Subcrureus* in the lower limb, but it is not a separate muscle.

Nerves.—The *Triceps* is supplied by the seventh and eighth cervical nerves through the musculo-spiral nerve.

Actions.—The *Triceps* is the great extensor muscle of the forearm, serving, when the forearm is flexed, to extend the elbow-joint. It is the direct antagonist of the *Biceps* and *Brachialis anticus*. When the arm is extended the long head of the muscle may assist the *Teres major* and *Latissimus dorsi* in drawing the humerus backward and in adducting it to the thorax. The long head of the *Triceps* protects the under part of the shoulder-joint, and prevents displacement of the head of the humerus downward and backward. The *Subanconeus* draws up the posterior ligament during extension of the forearm.

Surgical Anatomy.—The existence of the band of fibres from the *Triceps* to the fascia of the forearm is of importance in excision of the elbow, and should always be carefully preserved from injury by the operator, as by means of these fibres the patient is enabled to extend the forearm, a movement which would otherwise mainly be accomplished by gravity; that is to say, allowing the forearm to drop from its own weight.

III. MUSCLES AND FASCLE OF THE FOREARM.

Dissection.—To dissect the forearm, place the limb in the position indicated in Fig. 228; make a vertical incision along the middle line from the elbow to the wrist, and a transverse incision at the extremity of this; the superficial structures being removed, the deep fascia of the forearm is exposed.

The **deep fascia** of the forearm, continuous above with that enclosing the arm, is a dense, highly glistening aponeurotic investment, which forms a general sheath enclosing the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and gives off from its inner surface numerous intermuscular septa, which enclose each muscle separately. Below, it is continuous in front with the anterior annular ligament, and forms a sheath for the tendon of the *Palmaris longus* muscle, which passes over the annular ligament to be inserted into the palmar fascia. Behind, near the wrist-joint, it becomes much thickened by the addition of many transverse fibres, and forms the posterior annular ligament. It consists of circular and oblique fibres, connected together by numerous vertical fibres. It is much thicker on the dorsal than on the palmar surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the *Brachialis anticus* and *Biceps* in front, and from the *Triceps* behind. Its deep surface gives origin to muscular fibres, especially at the upper part of the inner and outer sides of the forearm, and forms the boundaries of a series of conical-shaped cavities, in which the muscles are contained. Besides the vertical septa separating each muscle, transverse septa are given off both on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layer of muscles. Numerous apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size, situated at the front of the elbow, serves for the passage of a communicating branch between the superficial and deep veins.

The muscles of the forearm may be subdivided into groups corresponding to the region they occupy. One group occupies the inner and anterior aspect of the forearm, and comprises the *Flexor* and *Pronator* muscles. Another group occupies its outer side, and a third its posterior aspect. The two latter groups include all the *Extensor* and *Supinator* muscles.

8. Anterior Radio-ulnar Region.

The muscles in this region are divided for convenience of description into two groups or layers, superficial and deep.

Superficial Layer.

<i>Pronator radii teres.</i>	<i>Flexor carpi ulnaris.</i>
<i>Flexor carpi radialis.</i>	<i>Flexor sublimis digitorum.</i>
<i>Palmaris longus.</i>	

These muscles take origin from the internal condyle of the humerus by a common tendon.

The ***Pronator radii teres*** arises by two heads. One, the larger and more superficial, arises from the humerus, immediately above the internal condyle, and from the tendon common to the origin of the other muscles; also from the fascia of the forearm and intermuscular septum between it and the *Flexor carpi radialis*. The other head is a thin fasciculus which arises from the inner side of the coronoid process of the ulna, joining the preceding at an acute angle. Between the two heads the median nerve enters the forearm. The muscle passes obliquely across the forearm from the inner to the outer side, and terminates in a flat tendon, which turns over the outer margin of the radius, and is inserted into a rough impression at the middle of the outer surface of the shaft of that bone.

Relations.—By its *anterior surface*, throughout the greater part of its extent, with the deep fascia; at its insertion it is crossed by the radial vessels and nerve, and covered by the *Supinator longus*; by its *posterior surface*, with the *Brachialis anticus*, *Flexor sublimis digitorum*, the median nerve, and ulnar artery, the small or deep head being interposed between the two latter structures. Its *outer border* forms the inner boundary of a triangular space in which are placed the brachial artery, median nerve, and tendon of the *Biceps* muscle. Its *inner border* is in contact with the *Flexor carpi radialis*.

Surgical Anatomy.—This muscle, when suddenly brought into very active use, as in the game of lawn tennis, is apt to be strained, producing slight swelling, tenderness, and pain on putting the muscle into action. This is known as "lawn-tennis arm."

The **Flexor carpi radialis** lies on the inner side of the preceding muscle. It arises from the internal condyle by the common tendon, from the fascia of the forearm, and from the intermuscular septa between it and the Pronator radii teres, on the outside, the Palmaris longus internally, and the Flexor sublimis digitorum beneath. Slender and aponeurotic in structure at its commencement, it increases in size, and terminates in a tendon which forms rather more than the lower half of its length. This tendon passes through a canal on the outer side of the annular ligament, runs through a groove in the os trapezium (which is converted into a canal by a fibrous sheath, and lined by a synovial membrane), and is inserted into the base of the metacarpal bone of the index finger, and by a slip into the base of the metacarpal bone of the middle finger. The radial artery lies between the tendon of this muscle and the Supinator longus, and may easily be tied in this situation.

Relations.—By its *superficial surface*, with the deep fascia and the integument; by its *deep surface*, with the Flexor sublimis digitorum, Flexor longus pollicis, and wrist-joint; by its *outer border*, with the Pronator radii teres and the radial vessels; by its *inner border*, with the palmaris longus above and the median nerve below.

The **Palmaris longus** is a slender, fusiform muscle lying on the inner side of the preceding. It arises from the inner condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. It terminates in a slender flattened tendon, which passes over the upper part of the annular ligament, to end in the central part of the palmar fascia and lower part of the annular ligament, frequently sending a tendinous slip to the short muscles of the thumb. This muscle is often absent, and is subject to very considerable variations: it may be tendinous above and muscular below; or it may be muscular in the centre, with a tendon above and below; or it may present two muscular bundles with a central tendon; or finally it may consist simply of a mere tendinous band.

Relations.—By its *superficial surface*, with the deep fascia. By its *deep surface*, with the Flexor sublimis digitorum. *Internally*, with the Flexor carpi ulnaris. *Externally*, with the Flexor carpi radialis. The median nerve lies close to the tendon, just above the wrist, on its inner and posterior side.

The **Flexor carpi ulnaris** lies along the ulnar side of the forearm. It arises by two heads, connected by a tendinous arch, beneath which pass the ulnar nerve and posterior ulnar recurrent artery. One head arises from the inner condyle of the humerus by the common tendon; the other from the inner margin of the olecranon and from the upper two-thirds of the posterior border of the ulna by an aponeurosis, common

FIG. 233.—Front of the left forearm. Superficial muscles.

to it and the Extensor carpi ulnaris and Flexor profundus digitorum; and from the intermuscular septum between it and the Flexor sublimis digitorum. The fibres terminate in a tendon which occupies the anterior part of the lower half of the muscle, and is inserted into the pisiform bone, and is prolonged from this to the fifth metacarpal and unciform bones, by the piso-metacarpal and piso-uncinate ligaments: it is also attached by a few fibres to the annular ligament. The ulnar artery lies on the outer side of the tendon of this muscle, in the lower two-thirds of the forearm, the tendon forming a guide in tying the vessel in this situation.

Relations.—By its *superficial surface*, with the deep fascia, with which it is intimately connected for a considerable extent; by its *deep surface*, with the Flexor sublimis digitorum, the Flexor profundus digitorum, the Pronator quadratus, and the ulnar vessels and nerve; by its *outer or radial border*, with the Palmaris longus above and the ulnar vessels and nerve below.

The **Flexor sublimis digitorum (perforatus)** is placed beneath the preceding muscles, which therefore must be removed in order to bring its attachment into view. It is the largest of the muscles of the superficial layer, and arises by three heads. One head arises from the internal condyle of the humerus by the common tendon, from the internal lateral ligament of the elbow-joint, and from the intermuscular septum common to it and the preceding muscles. The second head arises from the inner side of the coronoid process of the ulna, above the ulnar origin of the Pronator radii teres (Fig. 100, p. 151). The third head arises from the oblique line of the radius, extending from the tubercle to the insertion of the Pronator radii teres. The fibres pass vertically downward, forming a broad and thick muscle, which speedily divides into two planes of muscular fibres, superficial and deep: the superficial plane divides into two parts which end in tendons for the middle and ring fingers; the deep plane also divides into two parts, which end in tendons for the index and little fingers, but previously to having done so, it gives off a muscular slip, which joins that part of the superficial plane which is intended for the ring finger. As the four tendons thus formed pass beneath the annular ligament into the palm of the hand, they are arranged in pairs, the superficial pair corresponding to the middle and ring fingers, the deep pair to the index and little fingers. The tendons diverge from one another as they pass onward. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor profundus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying deep flexor tendon. Finally they subdivide a second time, to be inserted into the sides of the second phalanges about their middle. After leaving the palm, these tendons, accompanied by the deep flexor tendons, lie in osseo-aponeurotic canals (Fig. 234). These canals are formed by strong fibrous bands, which arch across the tendons, and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely; but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane, which is reflected on the contained tendons.

Relations.—In the forearm, by its *superficial surface*, with the deep fascia and all the preceding superficial muscles; by its *deep surface*, with the Flexor profundus digitorum, Flexor longus pollicis, the ulnar vessels and nerve, and the median nerve. In the hand its tendons are in relation, *in front*, with the palmar fascia, superficial palmar arch, and the branches of the median nerve; *behind*, with the tendons of the deep Flexor and the Lumbricales.

Deep Layer.

Flexor profundus digitorum.

Flexor longus pollicis.

Pronator quadratus.

Dissection.—Divide each of the superficial muscles at its centre, and turn either end aside; the deep layer of muscles, together with the median nerve and ulnar vessels, will then be exposed.

The **Flexor profundus digitorum** (**perforans**) (Fig. 234) is situated on the ulnar side of the forearm, immediately beneath the superficial Flexors. It arises from the upper three-fourths of the anterior and inner surfaces of the shaft of the ulna, embracing the insertion of the Brachialis anticus above, and extending, below, to within a short distance of the Pronator quadratus. It also arises from a depression on the inner side of the coronoid process; by an aponeurosis from the upper three-fourths of the posterior border of the ulna, in common with the Flexor and Extensor carpi ulnaris; and from the ulnar half of the interosseous membrane. The fibres form a fleshy belly of considerable size, which divides into four tendons: these pass under the annular ligament beneath the tendons of the Flexor sublimis digitorum. Opposite the first phalanges the tendons pass through the openings in the two slips of the tendons of the Flexor sublimis digitorum, and are finally inserted into the bases of the last phalanges. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the three inner fingers are connected together by cellular tissue and tendinous slips as far as the palm of the hand. The tendons of this muscle and those of the Flexor sublimis digitorum, whilst contained in the osseo-aponeurotic canals of the fingers, are invested in a synovial sheath, and are connected to each other and to the phalanges by slender tendinous filaments, called *vincula accessoria tendinum*. One of these connects the deep tendon to the bone before it passes through the superficial tendon; a second connects the two tendons together, after the deep tendons have passed through; and a third connects the deep tendon to the head of the second phalanx. This last consists largely of yellow elastic tissue, and may assist in drawing down the tendon after flexion of the finger.¹

Four small muscles, the Lumbricales, are connected with the tendons of the Flexor profundus in the palm. They will be described with the muscles in that region.

FIG. 234.—Front of the left forearm. Deep muscles.

¹ Marshall, *Brit. and For. Med.-Chir. Rev.*, 1853.

Relations.—By its *superficial surface*, in the forearm, with the Flexor sublimis digitorum, the Flexor carpi ulnaris, the ulnar vessels and nerve, and the median nerve; and in the hand, with the tendons of the superficial Flexor; by its *deep surface*, in the forearm, with the ulna, the interosseous membrane, the Pronator quadratus; and in the hand, with the interossei, Adductor pollicis, and deep palmar arch; by its *ulnar border*, with the Flexor carpi ulnaris; by its *radial border*, with the Flexor longus pollicis, the anterior interosseous vessels and nerve being interposed.

The **Flexor longus pollicis** is situated on the radial side of the forearm, lying on the same plane as the preceding. It arises from the grooved anterior surface of the shaft of the radius, commencing above, immediately below the tuberosity and oblique line, and extending below to within a short distance of the Pronator quadratus. It also arises from the adjacent part of the interosseous membrane, and generally by a fleshy slip from the inner border of the coronoid process or from the internal condyle of the humerus. The fibres pass downward, and terminate in a flattened tendon which passes beneath the annular ligament, is then lodged in the interspace between the outer head of the Flexor brevis pollicis and the Adductor obliquus pollicis, and, entering an osseo-aponeurotic canal similar to those for the other flexor tendons, is inserted into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the Flexor sublimis digitorum, Flexor carpi radialis, Supinator longus, and radial vessels; by its *deep surface*, with the radius, interosseous membrane, and Pronator quadratus; by its *ulnar border*, with the Flexor profundus digitorum, from which it is separated by the anterior interosseous vessels and nerve.

The **Pronator quadratus** is a small, flat, quadrilateral muscle, extending transversely across the front of the radius and ulna, above their carpal extremities. It arises from the oblique or pronator ridge on the lower part of the anterior surface of the shaft of the ulna; from the lower fourth of the anterior surface and the anterior border of the ulna; and from a strong aponeurosis which covers the inner third of the muscle. The fibres pass outward and slightly downward, to be inserted into the lower fourth of the anterior surface and anterior border of the shaft of the radius.

Relations.—By its *superficial surface*, with the Flexor profundus digitorum, the Flexor longus pollicis, Flexor carpi radialis, and the radial vessels; by its *deep surface*, with the radius, ulna, and interosseous membrane.

Nerves.—All the muscles of the superficial layer are supplied by the median nerve, excepting the Flexor carpi ulnaris, which is supplied by the ulnar. The Pronator radii teres and the Flexor carpi radialis derive their supply primarily from the sixth cervical; the Palmaris longus from the eighth cervical; the Flexor sublimis digitorum from the seventh and eighth cervical and first dorsal, and the Flexor carpi ulnaris from the eighth cervical and first dorsal nerves. Of the deep layer, the Flexor profundus digitorum is supplied by the eighth cervical and first dorsal through the ulnar and anterior interosseous branch of the median. The remaining two muscles, Flexor longus pollicis and Pronator quadratus, are also supplied by the eighth cervical and first dorsal through the anterior interosseous branch of the median.

Actions.—These muscles act upon the forearm, the wrist, and hand. The Pronator radii teres helps to rotate the radius upon the ulna, rendering the hand prone: when the radius is fixed it assists the other muscles in flexing the forearm. The Flexor carpi radialis is one of the flexors of the wrist; when acting alone it flexes the wrist, inclining it to the radial side. It can also assist in pronating the forearm and hand, and, by continuing its action, to bend the elbow. The Flexor carpi ulnaris is one of the flexors of the wrist: when acting alone it flexes the wrist, inclining it to the ulnar side, and, by continuing to contract, it bends the elbow. The Palmaris longus is a tensor of the palmar fascia. It also assists in flexing the wrist and elbow. The Flexor sublimis

digitorum flexes first the middle and then the approximal phalanx. It assists in flexing the wrist and elbow. The Flexor profundus digitorum is one of the flexors of the phalanges. After the Flexor sublimis has bent the second phalanx, the Flexor profundus flexes the terminal one, but it cannot do so until after the contraction of the superficial muscle. It also assists in flexing the wrist. The Flexor longus pollicis is a flexor of the phalanges of the thumb. When the thumb is fixed it also assists in flexing the wrist. The Pronator quadratus helps to rotate the radius upon the ulna, rendering the hand prone.

9. Radial Region (Fig. 235).

Supinator longus.

Extensor carpi radialis longior.

Extensor carpi radialis brevior.

Dissection.—Divide the integument in the same manner as in the dissection of the anterior brachial region, and, after having examined the cutaneous vessels and nerves and deep fascia, remove all those structures. The muscles will then be exposed. The removal of the fascia will be considerably facilitated by detaching it from below upward. Great care should be taken to avoid cutting across the tendons of the muscles of the thumb, which cross obliquely the larger tendons running down the back of the radius.

The **Supinator longus** (brachioradialis) is the most superficial muscle on the radial side of the forearm; it is fleshy for the upper two-thirds of its extent, tendinous below. It arises from the upper two-thirds of the external supracondylar ridge of the humerus, and from the external intermuscular septum, being limited above by the musculo-spiral groove. The fibres terminate above the middle of the forearm in a flat tendon, which is inserted into the outer side of the base of the styloid process of the radius.

Relations.—By its *superficial surface*, with the integument and fascia for the greater part of its extent; near its insertion it is crossed by the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis; by its *deep surface*, with the humerus, the Extensor carpi radialis longior and brevior, the insertion of the Pronator radii teres, and the Supinator brevis;

FIG. 235.—Posterior surface of the forearm. Superficial muscles.

by its *inner border*, above the elbow, with the Brachialis anticus, the musculospiral nerve, and radial recurrent artery; and in the forearm with the radial vessels and nerve.

The **Extensor carpi radialis longior** is placed partly beneath the preceding muscle. It arises from the lower third of the external supracondylar ridge of the humerus, and from the external intermuscular septum by a few fibres from the common tendon of origin of the Extensor muscles of the forearm. The fibres terminate at the upper third of the forearm in a flat tendon, which runs along the outer border of the radius, beneath the extensor tendons of the thumb; it then passes through a groove common to it and the Extensor carpi radialis brevis, immediately behind the styloid process, and is inserted into the base of the metacarpal bone of the index finger, on its radial side.

Relations.—By its *superficial surface*, with the Supinator longus and fascia of the forearm; its *outer side* is crossed obliquely by the extensor tendons of the thumb; by its *deep surface*, with the elbow-joint, the Extensor carpi radialis brevis, and back part of the wrist.

The **Extensor carpi radialis brevis** is shorter, as its name implies, and thicker than the preceding muscle, beneath which it is placed. It arises from the external condyle of the humerus by a tendon common to it and the three following muscles; from the external lateral ligament of the elbow-joint, from a strong aponeurosis which covers its surface, and from the intermuscular septa between it and the adjacent muscles. The fibres terminate about the middle of the forearm in a flat tendon which is closely connected with that of the preceding muscle, and accompanies it to the wrist, lying in the same groove on the posterior surface of the radius; it passes beneath the extensor tendons of the thumb, then beneath the annular ligament, and, diverging somewhat from its fellow, is inserted into the base of the metacarpal bone of the middle finger, on its radial side.

The tendons of the two preceding muscles pass through the same compartment of the annular ligament, and are lubricated by a single synovial membrane, but are separated from each other by a small vertical ridge of bone as they lie in the groove at the back of the radius.

Relations.—By its *superficial surface*, with the Extensor carpi radialis longior, and with the Extensor muscles of the thumb which cross it; by its *deep surface*, with the Supinator brevis, tendon of the Pronator radii teres, radius, and wrist-joint; by its *ulnar border*, with the Extensor communis digitorum.

10. Posterior Radio-ulnar Region (Fig. 235).

The muscles in this region are divided for purposes of description into two groups or layers, superficial and deep.

Superficial Layer.

Extensor communis digitorum.

Extensor carpi ulnaris.

Extensor minimi digiti.

Anconeus.

The **Extensor communis digitorum** is situated at the back part of the forearm. It arises from the external condyle of the humerus by the common tendon, from the deep fascia, and the intermuscular septa between it and the adjacent muscles. Just below the middle of the forearm it divides into three fleshy masses, from which tendons proceed; these pass, together with the Extensor indicis, through a separate compartment of the annular ligament, lubricated by a synovial membrane. The tendons then diverge, the innermost one dividing into two; and all, after passing across the back of the hand, are inserted into the second and third phalanges of the fingers in the following manner: the outermost tendon, accompanied by the Extensor indicis, goes to the index finger; the second tendon is sometimes connected to the first by a thin transverse band, and receives a slip from the third tendon; it goes to the middle finger; the third tendon gives off

the slip to the second, and receives a very considerable part of the fourth tendon; the fourth, or innermost tendon, divides into two parts: one goes to join the third tendon, the other, reinforced by the Extensor minimi digiti, goes to the little finger. Each tendon opposite the metacarpo-phalangeal articulation becomes narrow and thickened, and gives off a thin fasciculus upon each side of the joint, which blends with the lateral ligaments and serves as the posterior ligament; after having passed the joint it spreads out into a broad aponeurosis, which covers the whole of the dorsal surface of the first phalanx, being reinforced, in this situation, by the tendons of the Interossei and Lumbricales. Opposite the first phalangeal joint this aponeurosis divides into three slips, a middle and two lateral: the former is inserted into the base of the second phalanx; and the two lateral, which are continued onward along the sides of the second phalanx, unite by their contiguous margins, and are inserted into the dorsal surface of the last phalanx. As the tendons cross the phalangeal joints they furnish them with posterior ligaments.

Relations.—By its *superficial surface*, with the fascia of the forearm and hand, the posterior annular ligament, and integument; by its *deep surface*, with the Supinator brevis, the Extensor muscles of the thumb and index finger, the posterior interosseous vessels and nerve, the wrist-joint, carpus, metacarpus, and phalanges; by its *radial border*, with the Extensor carpi radialis brevis; by its *ulnar border*, with the Extensor minimi digiti and Extensor carpi ulnaris.

The **Extensor minimi digiti** is a slender muscle placed on the inner side of the Extensor communis, with which it is generally connected. It arises from the common tendon by a thin, tendinous slip, and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a separate compartment in the annular ligament behind the inferior radio-ulnar joint, then divides into two as it crosses the hand, the outermost division being joined by the slip from the innermost tendon of the common extensor. The two slips thus formed spread into a broad aponeurosis, which after receiving a slip from the Abductor minimi digiti is inserted into the second and third phalanges. The tendon is situated on the ulnar side of, and somewhat more superficial than, the common extensor.

The **Extensor carpi ulnaris** is the most superficial muscle on the ulnar side of the forearm. It arises from the external condyle of the humerus by the common tendon; by an aponeurosis from the posterior border of the ulna in common with the Flexor carpi ulnaris and the Flexor profundus digitorum; and from the deep fascia of the forearm. This muscle terminates in a tendon which runs through a groove behind the styloid process of the ulna, passes through a separate compartment in the annular ligament, and is inserted into the prominent tubercle on the ulnar side of the base of the metacarpal bone of the little finger.

Relations.—By its *superficial surface*, with the deep fascia of the forearm; by its *deep surface*, with the ulna and the muscles of the deep layer.

The **Anconeus** is a small triangular muscle placed behind and below the elbow-joint, and appears to be a continuation of the external portion of the Triceps. It arises by a separate tendon from the back part of the outer condyle of the humerus, and is inserted into the side of the olecranon and upper fourth of the posterior surface of the shaft of the ulna; its fibres diverge from their origin, the upper ones being directed transversely, the lower obliquely inward.

Relations.—By its *superficial surface*, with a strong fascia derived from the Triceps; by its *deep surface*, with the elbow-joint, the orbicular ligament, the ulna, and a small portion of the Supinator brevis.

Deep Layer (Fig. 237).

Supinator brevis.

Extensor ossis metacarpi pollicis.

Extensor indicis.

Extensor brevis pollicis.

Extensor longus pollicis.

The **Supinator brevis** (Fig. 236) is a broad muscle, of hollow cylindrical form, curved round the upper third of the radius. It consists of two distinct planes of muscular fibres, between which lies the posterior interosseous nerve. The two planes arise in common: the superficial one by tendinous, and the deeper by muscular, fibres from the external condyle of the humerus; from the external lateral ligament of the elbow-joint and the orbicular ligament of the radius; from the ridge on the ulna, which runs obliquely downward from the posterior extremity of the lesser sigmoid cavity; from the triangular depression in front of it; and from a tendinous expansion which covers the surface of the muscle. The superficial fibres surround the upper part of

FIG. 236.—Supinator brevis. (From a preparation in the Museum of the Royal College of Surgeons of England.)

FIG. 237.—Posterior surface of the forearm. Deep muscles.

the radius, and are inserted into the outer edge of the bicipital tuberosity and to the oblique line of the radius, as low down as the insertion of the Pronator radii teres. The upper fibres of the deeper plane form a sling-like fasciculus, which encircles the neck of the radius above the tuberosity and is

attached to the back part of its inner surface: the greater part of this portion of the muscle is inserted into the posterior and external surface of the shaft, midway between the oblique line and the head of the bone. Between the insertion of the two planes the posterior interosseous nerve lies on the shaft of the bone.

Relations.—By its *superficial surface*, with the superficial Extensor and Supinator muscles, and the radial vessels and nerve; by its *deep surface*, with the elbow-joint, the interosseous membrane, and the radius.

The **Extensor ossis metacarpi pollicis** is the most external and the largest of the deep extensor muscles: it lies immediately below the Supinator brevis, with which it is sometimes united. It arises from the outer part of the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the shaft of the radius. Passing obliquely downward and outward, it terminates in a tendon which runs through a groove on the outer side of the styloid process of the radius, accompanied by the tendon of the Extensor brevis pollicis, and is inserted into the base of the metacarpal bone of the thumb. It occasionally gives off two slips near its insertion—one to the Trapezium, and the other to blend with the origin of the Abductor pollicis.

Relations.—By its *superficial surface*, with the Extensor communis digitorum, Extensor minimi digiti, and fascia of the forearm, and with the branches of the posterior interosseous artery and nerve which cross it; by its *deep surface*, with the ulna, interosseous membrane, radius, the tendons of the Extensor carpi radialis longior and brevior, which it crosses obliquely, and, at the outer side of the wrist, with the radial vessels; by its *upper border*, with the Supinator brevis; by its *lower border*, with the Extensor brevis pollicis.

The **Extensor brevis pollicis** (*Extensor primi internodii pollicis*), the smallest muscle of this group, lies on the inner side of the preceding. It arises from the posterior surface of the shaft of the radius, below the Extensor ossis metacarpi pollicis, and from the interosseous membrane. Its direction is similar to that of the Extensor ossis metacarpi pollicis, its tendon passing through the same groove on the outer side of the styloid process, to be inserted into the base of the first phalanx of the thumb.

Relations.—The same as those of the Extensor ossis metacarpi pollicis.

The **Extensor longus pollicis** (*Extensor secundi internodii pollicis*) is much larger than the preceding muscle, the origin of which it partly covers in. It arises from the outer part of the posterior surface of the shaft of the ulna, below the origin of the Extensor ossis metacarpi pollicis, and from the interosseous membrane. It terminates in a tendon which passes through a separate compartment in the annular ligament, lying in a narrow, oblique groove at the back part of the lower end of the radius. It then crosses obliquely the tendons of the Extensor carpi radialis longior and brevior, being separated from the other extensor tendons of the thumb by a triangular interval, in which the radial artery is found, and is finally inserted into the base of the last phalanx of the thumb.

Relations.—By its *superficial surface*, with the same parts as the Extensor ossis metacarpi pollicis; by its *deep surface*, with the ulna, interosseous membrane, the posterior interosseous nerve, radius, the wrist, the radial vessels, and metacarpal bone of the thumb.

The **Extensor indicis** is a narrow, elongated muscle placed on the inner side of, and parallel with, the preceding. It arises from the posterior surface of the shaft of the ulna, below the origin of the Extensor longus pollicis and from the interosseous membrane. Its tendon passes with the Extensor communis digitorum through the same canal in the annular ligament, and subsequently joins the tendon of the Extensor communis which belongs to the index finger, opposite the lower end of the corresponding metacarpal bone, lying to the ulnar side of the tendon from the common Extensor.

Relations.—The relations are similar to those of the preceding muscles.

Nerves.—The Supinator longus is supplied by the sixth, the Extensor carpi

radialis longior by the sixth and seventh, and the Anconeus by the seventh and eighth cervical nerves, all through the musculo-spiral nerve; the remaining muscles of the radial and posterior brachial region are supplied through the posterior interosseous nerve, the Supinator brevis being supplied by the sixth cervical, the Extensor carpi radialis brevior by the sixth and seventh cervical, and all the other muscles by the seventh cervical.

Actions.—The muscles of the radial and posterior brachial regions, which comprise all the extensor and supinator muscles, act upon the forearm, wrist, and hand; they are the direct antagonists of the pronator and flexor muscles. The Anconeus assists the Triceps in extending the forearm. The chief action of the Supinator longus is that of a flexor of the elbow-joint, but in addition to this it may act both as a supinator or a pronator; that is to say, if the forearm is forcibly pronated it will act as a supinator, and bring the bones into a position midway between supination and pronation; and, *vice versa*, if the arm is forcibly supinated, it will act as a pronator, and bring the bones into the same position, midway between supination and pronation. The action of the muscle is therefore to throw the forearm and hand into the position they naturally occupy when placed across the chest. The Supinator brevis is a supinator; that is to say, when the radius has been carried across the ulna in pronation and the back of the hand is directed forward, this muscle carries the radius back again to its normal position on the outer side of the ulna, and the palm of the hand is again directed forward. The Extensor carpi radialis longior extends the wrist and abducts the hand. It may also assist in bending the elbow-joint; at all events, it serves to fix or steady this articulation. The Extensor carpi radialis brevior assists the Extensor carpi radialis longior in extending the wrist, and may also act slightly as an abductor of the hand. The Extensor carpi ulnaris helps to extend the hand, but when acting alone inclines it toward the ulnar side; by its continued action it extends the elbow-joint. The Extensor communis digitorum extends the phalanges, then the wrist, and finally the elbow. It acts principally on the proximal phalanges, the middle and terminal phalanges being extended by the Interossei and Lumbricales. It has also a tendency to separate the fingers as it extends them. The Extensor minimi digiti extends similarly the little finger, and by its continued action it assists in extending the wrist. It is owing to this muscle that the little finger can be extended or pointed whilst the others are flexed. The chief action of the Extensor ossis metacarpi pollicis is to carry the thumb outward and backward from the palm of the hand, and hence it has been called the *abductor pollicis longus*. By its continued action it helps to extend and abduct the wrist. The Extensor brevis pollicis extends the proximal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor longus pollicis extends the terminal phalanx of the thumb. By its continued action it helps to extend and abduct the wrist. The Extensor indicis extends the index finger, and by its continued action assists in extending the wrist. It is owing to this muscle that the index finger can be extended or pointed while the others are flexed.

Surgical Anatomy.—The tendons of the Extensor muscles of the thumb are liable to become strained and their sheaths inflamed after excessive exercise, producing a sausage-shaped swelling along the course of the tendon, and giving a peculiar creaking sensation to the finger when the muscle acts. In consequence of its often being caused by such movements as wringing clothes, it is known as “washerwoman’s sprain.”

IV. MUSCLES AND FASCIAE OF THE HAND.

The Muscles of the Hand are subdivided into three groups: 1. Those of the thumb, which occupy the radial side and produce the *thenar* eminence; 2. Those of the little finger, which occupy the ulnar side and give rise to the *hypothelar* eminence; 3. Those in the middle of the palm and within the interosseous spaces.

Dissection (Fig. 228).—Make a transverse incision across the front of the wrist, and a second across the heads of the metacarpal bones: connect the two by a vertical incision in the middle line, and continue it through the centre of the middle finger. The anterior and posterior annular ligaments and the palmar fascia should then be dissected.

The **Anterior Annular Ligament** is a strong, fibrous band which arches over the carpus, converting the deep groove on the front of the carpal bones into a canal, beneath which pass the flexor tendons of the fingers. It is attached, internally, to the pisiform bone and the hook of the ulniform bone, and externally to the tuberosity of the scaphoid and to the inner part of the anterior surface and the ridge on the trapezium. It is continuous, above, with the deep fascia of the forearm, of which it may be regarded as a thickened portion, and, below, with the palmar fascia. It is crossed by the ulnar vessels and nerve and the cutaneous branches of the median and ulnar nerves. At its outer extremity is the tendon of the Flexor carpi radialis, which lies in the groove on the trapezium between the attachments of the annular ligament to the bone. It has inserted into its anterior surface a part of the tendon of the Palmaris longus and part of the tendon of the Flexor carpi ulnaris, and has arising from it, below, the small

FIG. 228.—Transverse section through the wrist, showing the annular ligaments and the canals for the passage of the tendons.

FIG. 229.—Transverse section through the carpus, showing the relative positions of the tendons, vessels, and nerves. (Henle.)

muscles of the thumb and little finger. Beneath it pass the tendons of the Flexor sublimis and profundus digitorum, the Flexor longus pollicis, and the median nerve.

The Synovial Membranes of the Flexor Tendons at the Wrist.—There are two synovial membranes which enclose all the tendons as they pass beneath this ligament—one for the Flexor sublimis and profundus digitorum, the other for the Flexor longus pollicis. They extend up into the forearm for about an inch above the annular ligament, and downward about halfway along the metacarpal bone, where they terminate in a blind diverticulum around each pair of tendons, with the exception of that of the thumb and those of the little finger—in these two digits the diverticulum is continued on, and communicates with the synovial sheath of the tendons in the fingers. In the other three fingers the synovial sheath of the

tendons begins as a blind pouch without communication with the large synovial sac (Fig. 240).

Surgical Anatomy.—This arrangement of the synovial sheaths explains the fact that thecal abscess in the thumb and little finger is liable to be followed by abscesses in the forearm, from extension of the inflammation along the continuous synovial sheaths. Ganglion is apt to occur in this situation, constituting "compound palmar ganglion"; it presents an hour-glass outline, with a swelling in front of the wrist and in the palm of the hand, and a constriction corresponding to the annular ligament between the two. The fluid can be forced from the one swelling to the other under the ligament.

The **Posterior Annular Ligament** is a strong fibrous band extending obliquely downward and inward across the back of the wrist, and consisting of the deep fascia of the back of the forearm, strengthened by the addition of some transverse fibres. It binds down the extensor tendons in their passage to the fingers,

FIG. 240.—Diagram showing the arrangement of the synovial sheaths of the palm and fingers.

being attached, internally, to the styloid process of the ulna, the cuneiform and pisiform bones; externally, to the margin of the radius; and, in its passage across the wrist, to the elevated ridges on the posterior surface of the radius. It presents six compartments for the passage of tendons, each of which is lined by a separate synovial membrane. These are, from without inward—1. On the outer side of the styloid process, for the tendons of the Extensor ossis metacarpi and Extensor brevis pollicis; 2. Behind the styloid process, for the tendons of the Extensor carpi radialis longior and brevior; 3. About the middle of the posterior surface of the radius, for the tendon of the Extensor longus pollicis; 4. To the inner side of the latter, for the tendons of the Extensor communis digitorum and Extensor indicis; 5. Opposite the interval between the radius and ulna, for the Extensor minimi digiti; 6. Grooving the back of the ulna, for the tendon of the Extensor carpi ulnaris.

The synovial membranes lining these sheaths are usually very extensive, reaching from above the annular ligament, down upon the tendons for a variable distance on the back of the hand.

The **deep palmar fascia** (Fig. 241) forms a common sheath which invests the muscles of the hand. It consists of a central and two lateral portions.

The *central portion* occupies the middle of the palm, is triangular in shape, of great strength and thickness, and binds down the tendons and protects the vessels and nerves in this situation. It is narrow above, where it is attached to the lower margin of the annular ligament, and receives the expanded tendon of the Palmaris longus muscle. Below, it is broad and expanded, and divides into four slips for the four fingers. Each slip gives off superficial fibres, which are inserted into the skin of the palm and finger, those to the palm joining the skin at the furrow corresponding to the metacarpo-phalangeal articulation, and those to the fingers passing into the skin at the transverse fold at the base of the fingers. The deeper part of each slip subdivides into two processes, which are inserted into the lateral margins of the anterior (glenoid) ligament of the metacarpo-phalangeal joint. From the sides of these processes offsets are sent backward, to be attached to the borders of the lateral surfaces of

the metacarpal bones at their distal extremities. By this arrangement short channels are formed on the front of the lower ends of the metacarpal bones, through which the flexor tendons pass. Dr. W. W. Keen describes a fifth slip as frequently found passing to the thumb. The intervals left in the fascia between the four fibrous slips transmit the digital vessels and nerves and the tendons of the Lumbricales. At the points of division of the palmar fascia into the slips above mentioned numerous strong, transverse fibres bind the separate processes together. The palmar fascia is intimately adherent to the integument by dense fibro-areolar tissue, forming the superficial palmar fascia, and gives origin by its inner margin to the *Palmaris brevis*: it covers the superficial palmar arch, the

FIG. 241.—Palmar fascia. (From a preparation in the Museum of the Royal College of Surgeons of England.)

tendons of the flexor muscles, and the branches of the median and ulnar nerves, and on each side it gives off a vertical septum, which is continuous with the interosseous aponeurosis and separates the lateral from the middle palmar group of muscles.

The *lateral portions* of the palmar fascia are thin, fibrous layers, which cover, on the radial side, the muscles of the ball of the thumb, and, on the ulnar side, the muscles of the little finger; they are continuous with the dorsal fascia, and in the palm with the central portion of the palmar fascia.

The **Superficial Transverse Ligament of the Fingers** is a thin, fibrous band which stretches across the roots of the four fingers, and is closely attached to the skin of the clefts, and internally to the fifth metacarpal bone, forming a sort of rudimentary web. Beneath it the digital vessels and nerves pass onward to their destination.

Surgical Anatomy.—The palmar fascia is liable to undergo contraction, producing a very inconvenient deformity known as “Dupuytren’s contraction.” The ring and little fingers are most frequently implicated, but the middle, the index, and the thumb may be involved. The proximal phalanx is drawn down and cannot be straightened, and the two distal phalanges become similarly flexed as the disease advances.

2. Radial Region (Figs. 242, 243).

Abductor pollicis.	Flexor brevis pollicis.
Opponens (Flexor ossis metacarpi) pollicis.	Abductor obliquus pollicis.
Adductor transversus pollicis.	

The **Abductor pollicis** is a thin, flat muscle, placed immediately beneath the integument. It arises from the annular ligament, the tuberosity of the scaphoid, and the ridge of the trapezium, frequently by two distinct slips; and, passing outward and downward, is inserted by a thin, flat tendon into the radial side of the base of the first phalanx of the thumb, sending a slip to join the tendon of the Extensor longus pollicis.

Relations.—By its *superficial surface*, with the palmar fascia and superficialis volæ artery, which frequently perforates it. By its *deep surface*, with the Opponens pollicis, from which it is separated by a thin aponeurosis. Its *inner border* is separated from the Flexor brevis pollicis by a narrow cellular interval.

The **Opponens pollicis** (*Flexor ossis metacarpi pollicis*) is a small, triangular muscle, placed beneath the preceding. It arises from the palmar surface of the ridge on the trapezium and from the annular ligament, passes downward and outward, and is inserted into the whole length of the metacarpal bone of the thumb on its radial side.

Relations.—By its *superficial surface*, with the Abductor and Flexor brevis pollicis. By its *deep surface*, with the trapezio-metacarpal articulation. By its *inner border*, with the Adductor obliquus pollicis.

The **Flexor brevis pollicis** consists of two portions, outer and inner. The outer and more superficial portion arises from the outer two-thirds of the lower border of the annular ligament, and passes along the outer side of the tendon of the Flexor longus pollicis; and, becoming tendinous, has a sesamoid bone developed in its tendon, and is inserted into the outer side of the base of the first phalanx of the thumb. The inner and deeper portion of the muscle is very small, and arises from the ulnar side of the first metacarpal bone beneath the Adductor obliquus pollicis, and is inserted into the inner side of the base of the first phalanx with this muscle.

Relations.—By its *superficial surface*, with the palmar fascia. By its *deep surface*, with the tendon of the Flexor longus pollicis. By its *external surface*, with the Opponens pollicis. *Behind*, with the Adductor obliquus pollicis.

The **Adductor obliquus pollicis** arises by several slips from the os magnum, the bases of the second and third metacarpal bones, the anterior carpal ligaments, and the sheath of the tendon of the Flexor carpi radialis. From this origin the greater number of fibres pass obliquely downward and converge to a tendon, which, uniting with the tendons of the deeper portion of the Flexor brevis pollicis and the Adductor transversus, is inserted into the inner side of the base of the first phalanx of the thumb, a sesamoid bone being developed in the tendon of insertion. A considerable fasciculus, however, passes more obliquely outward beneath the tendon of the long flexor to join the superficial portion of the short flexor and the Abductor pollicis.¹

¹ This muscle was formerly described as the deep portion of the Flexor brevis pollicis.

Relations.—By its *superficial surface*, with the Flexor longus pollicis and the outer head of the Flexor brevis pollicis. Its *deep surface* is in relation with the deep palmar arch, which passes between the two adductors.

The **Adductor transversus pollicis** (Fig. 242) is the most deeply seated of this group of muscles. It is of a triangular form, arising, by its broad base, from the lower two-thirds of the metacarpal bone of the middle finger on its palmar surface; the fibres, proceeding outward, converge, to be inserted, with the inner part of the Flexor brevis pollicis, and the Adductor obliquus pollicis, into the ulnar side of the base of the first phalanx of the thumb. From the common tendon of insertion a slip is prolonged to the Extensor longus pollicis.

Relations.—By its *superficial surface*, with the Adductor obliquus pollicis, the tendons of the Flexor profundus, and the Lumbricales. Its *deep surface* covers the first two interosseous spaces, from which it is separated by a strong aponeurosis.

Three of these muscles of the thumb, the Abductor, the Adductor transversus, and the Flexor brevis pollicis, at their insertions give off fibrous expansions which

FIG. 242.—Muscles of thumb. (From a preparation in the Museum of the Royal College of Surgeons of England.)

join the tendon of the Extensor longus pollicis. This permits of flexion of the proximal phalanx and extension of the terminal phalanx at the same time. These expansions, originally figured by Albinus, have been more recently described by M. Duchenne (*Physiologie des Mouvements*).

Nerves.—The Abductor, Opponens, and outer head of the Flexor brevis pollicis are supplied by the sixth cervical through the median nerve; the inner head of the Flexor brevis, and the Adductors, by the eighth cervical through the ulnar nerve.

Actions.—The actions of the muscles of the thumb are almost sufficiently indicated by their names. This segment of the hand is provided with three extensors—an extensor of the metacarpal bone, an extensor of the first, and an extensor of the second phalanx; these occupy the dorsal surface of the forearm and hand.

There are also three flexors on the palmar surface—a flexor of the metacarpal bone, a flexor of the proximal, and a flexor of the terminal phalanx; there is also an Abductor and two Adductors. The Abductor pollicis moves the metacarpal bone of the thumb outward; that is, away from the index finger. The Flexor ossis metacarpi pollicis flexes the metacarpal bone—that is, draws it inward over the palm—and at the same time rotates the bone, so as to turn the ball of the thumb toward the fingers, thus producing the movement of opposition. The Flexor brevis pollicis flexes and adducts the proximal phalanx of the thumb. The Adductores pollicis move the metacarpal bone of the thumb inward; that is, toward the index finger. These muscles give to the thumb its extensive range of motion. It will be noticed, however, that in consequence of the position of the first metacarpal bone, these movements differ from the corresponding movements of the metacarpal bones of the other fingers. Thus extension of the thumb more nearly corresponds to the motion of abduction in the other fingers, and flexion to adduction.

12. Ulnar Region (Fig. 243).

Palmaris brevis.

Abductor minimi digiti.

Flexor brevis minimi digiti.

Opponens (Flexor ossis metacarpi) minimi digiti.

The **Palmaris brevis** is a thin quadrilateral muscle placed beneath the integument on the ulnar side of the hand. It arises by tendinous fasciculi from the annular ligament and palmar fascia; the fleshy fibres pass inward, to be inserted into the skin on the inner border of the palm of the hand.

Relations.—By its *superficial surface*, with the integument, to which it is intimately adherent, especially by its inner extremity; by its *deep surface*, with the inner portion of the palmar fascia, which separates it from the ulnar vessels and nerve, and from the muscles of the ulnar side of the hand.

The **Abductor minimi digiti** is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone and from the tendon of the Flexor carpi ulnaris, and terminates in a flat tendon, which divides into two slips; one is inserted into the ulnar side of the base of the first phalanx of the little finger. The other slip is inserted into the ulnar border of the aponeurosis of the Extensor minimi digiti.

Relations.—By its *superficial surface*, with the inner portion of the palmar fascia and the Palmaris brevis; by its *deep surface*, with the Flexor ossis metacarpi minimi digiti; by its *outer border*, with the Flexor brevis minimi digiti.

The **Flexor brevis minimi digiti** lies on the same plane as the preceding muscle, on its radial side. It arises from the convex aspect of the hook of the unciform bone and anterior surface of the annular ligament, and is inserted into the inner side of the base of the first phalanx of the little finger. It is separated from the Abductor at its origin by the deep branches of the ulnar artery and nerve. This muscle is sometimes wanting; the Abductor is then, usually, of large size.

Relations.—By its *superficial surface*, with the internal portion of the palmar fascia and the Palmaris brevis; by its *deep surface*, with the Opponens. The deep branch of the ulnar artery and the corresponding branch of the ulnar nerve pass between the Abductor and Flexor brevis minimi digiti muscles.

The **Opponens (Flexor ossis metacarpi) minimi digiti** (Fig. 234) is of a triangular form, and placed immediately beneath the preceding muscles. It arises from the convexity of the hook of the unciform bone and contiguous portion of the annular ligament; its fibres pass downward and inward, to be inserted into the whole length of the metacarpal bone of the little finger, along its ulnar margin.

Relations.—By its *superficial surface*, with the Flexor brevis and Abductor minimi digiti; by its *deep surface*, with the Interossei muscles in the fourth metacarpal space, the metacarpal bone, and the Flexor tendons of the little finger.

13. Middle Palmar Region.

Lumbricales.

Interossei dorsales.

Interossei palmares.

The **Lumbricales** (Fig. 243) are four small fleshy fasciculi, accessories to the deep Flexor muscle. They arise from the tendons of the deep Flexor: the first and second, from the radial side and palmar surface of the tendons of the index and middle fingers respectively; the third, from the contiguous sides of the tendons of the middle and ring fingers; and the fourth, from the contiguous sides of the tendons of the ring and little fingers. They pass to the radial side of the corresponding fingers, and opposite the metacarpo-phalangeal articulation each tendon is inserted into the tendinous expansion of the Extensor communis digitorum, covering the dorsal aspect of each finger.

The **Interossei** muscles (Figs. 244, 245) are so named from occupying the intervals between the metacarpal bones, and are divided into two sets, a dorsal and palmar.

The **Dorsal interossei** are four in number, larger than the palmar, and occupy the intervals between the metacarpal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the first phalanges and into the aponeurosis of the common Extensor tendon. Between the double origin of each of these muscles is a narrow triangular interval, through the first of which passes the radial artery; through the other three passes a perforating branch from the deep palmar arch.

The *First dorsal interosseous muscle*, or *Abductor indicis*, is larger than the others. It is flat, triangular in form, and arises by two heads, separated by a fibrous arch, for the passage of the radial artery from the dorsum to the palm of the hand. The outer head arises from the upper half of the ulnar border of the first metacarpal bone; the inner head, from almost the entire length of the radial border of the second metacarpal bone; the tendon is inserted into the radial side of the index finger. The *second* and *third dorsal interossei* are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The *fourth* is inserted into the ulnar side of the ring finger.

The **Palmar interossei**, three in number, are smaller than the Dorsal, and placed upon the palmar surface of the metacarpal bones, rather than between them. They arise from the entire length of the metacarpal bone of one finger, and are inserted into the side of the base of the first phalanx and aponeurotic expansion of the common extensor tendon of the same finger.

The *first* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the first phalanx of the index finger. The *second* arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The *third* arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with two Interossei muscles, with the exception of the little finger, in which the Abductor muscle takes the place of one of the pair.

Nerves.—The two outer Lumbricales are supplied by the sixth cervical nerve, through the third and fourth digital branches of the median nerve: the two inner Lumbricales and all the Interossei are supplied by the eighth cervical nerve, through the deep palmar branch of the ulnar nerve. Brooks states that the third lumbrical received a twig from the median in twelve out of twenty-one cases.

Actions.—The Palmar interossei muscles adduct the fingers to an imaginary line drawn longitudinally through the centre of the middle finger; and the Dorsal interossei abduct the fingers from that line. In addition to this, the Interossei, in

conjunction with the Lumbricales, *flex the first phalanges* at the metacarpo-phalangeal joints, and extend the second and third phalanges in consequence of their insertion into the expansion of the extensor tendons. The Extensor communis digitorum is believed to act almost entirely on the first phalanges.

SURFACE FORM OF THE UPPER EXTREMITY.

The *Pectoralis major* largely influences surface form and conceals a considerable part of the thoracic wall in front. Its sternal origin presents a festooned border which bounds and determines the width of the sternal furrow. Its clavicular origin is somewhat depressed and flattened, and between the two portions of the muscle is often an oblique depression which differentiates the one from the other. The outer margin of the muscle is generally well marked above, and bounds the infraclavicular fossa, a triangular interval which separates the *Pectoralis major* from the *Deltoid*. It gradually becomes less marked as it approaches the tendon of insertion, and becomes more closely blended with the *Deltoid* muscle. The lower border of the *Pectoralis major* forms the rounded anterior axillary fold, and corresponds with the direction of the fifth rib. The *Pectoralis minor* influences surface form. When the arm is raised its lowest slip of origin produces a local fulness just below the border of the anterior fold of the axilla, and so serves to break the sharp line of the lower border of the *Pectoralis major* muscle, which is produced when the arm is in this position. The origin of the *Serratus magnus* produces a very characteristic surface marking. When the arm is raised from the side in a well-developed subject, the five or six lower serrations are plainly discernible, forming a zigzag line, caused by the series of digitations, which diminish in size from above downward, and have their apices arranged in the form of a curve. When the arm is lying by the side, the first serration to appear, at the lower margin of the *Pectoralis major*, is the one attached to the fifth rib. The *Deltoid*, with the prominence of the upper extremity of the humerus, produces the rounded outline of the shoulder. It is rounder and fuller in front than behind, where it presents a somewhat flattened form. Its anterior border, above, presents a rounded, slightly curved eminence, which bounds externally the infraclavicular fossa; below, it is closely united with the

FIG. 244.—The Dorsal interossei of left hand.

FIG. 245.—The Palmar interossei of left hand.

Pectoralis major. Its posterior border is thin, flattened, and scarcely marked above; below, it is thicker and more prominent. When the muscle is in action, the middle portion becomes irregular, presenting alternate longitudinal elevations and depressions, the elevations corresponding to the fleshy portions, the depressions to the tendinous intersections of the muscle. The insertion of the *Deltoid* is marked by a depression on the outer side of the middle of the arm. Of the scapular muscles, the only one which materially influences surface form is the *Teres major*, which assists the *Latissimus dorsi* in forming the thick, rounded fold of the posterior boundary of the axilla. When the arm is raised, the *Coraco-brachialis* reveals itself as a long, narrow elevation which emerges from under cover of the anterior fold of the axilla and runs downward, internal to the shaft of the humerus. When the arm is hanging by the side, its

front and inner part presents the prominence of the Biceps, bounded on either side by an inter-muscular depression. This muscle determines the contour of the front of the arm, and extends from the anterior margin of the axilla to the bend of the elbow. Its upper tendons are concealed by the Pectoralis major and the Deltoid, and its lower tendon sinks into the space at the bend of the elbow. When the muscle is in a state of complete contraction—that is to say, when the forearm has been flexed and supinated—it presents a rounded convex form, bulged out laterally, and its length is diminished. On each side of the Biceps, at the lower part of the arm, the *Brachialis anticus* is discernible. On the outer side it forms a narrow eminence which extends some distance up the arm along the border of the Biceps. On the inner side it shows itself only as a little fulness just above the elbow. On the back of the arm the long head of the *Triceps* may be seen as a longitudinal eminence emerging from under cover of the Deltoid, and gradually merging into the longitudinal flattened plane of the tendon of the muscle on the lower part of the back of the arm. The tendon of insertion of the muscle extends about half-way up the back of the arm, where it forms an elongated flattened plane when the muscle is in action. Under similar conditions the surface forms produced by the three heads of the muscle are well seen. On the anterior aspect of the elbow are to be seen two muscular elevations, one on each side, separated above and converging below so as to form a triangular space. Of these, the inner elevation, consisting of the flexors and pronator, forms the prominence along the inner side and front of the forearm. It is a fusiform mass, pointed above at the internal condyle and gradually tapering off below. The *Pronator radii teres*, the innermost muscle of the group, forms the boundary of the triangular space at the bend of the elbow. It is shorter, less prominent, and more oblique than the outer boundary. The most prominent part of the eminence is produced by the *Flexor carpi radialis*, the muscle next in order on the inner side of the preceding one. It forms a rounded prominence above, and can be traced downward to its tendon, which can be felt lying on the front of the wrist, nearer to the radial than to the ulnar border, and to the inner side of the radial artery. The *Palmaris longus* presents no surface marking above, but below is the most prominent tendon on the front of the wrist, standing out, when the muscle is in action, as a sharp, tense cord beneath the skin. The *Flexor sublimis digitorum* does not directly influence surface form. The position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of the *Palmaris longus* and the *Flexor carpi ulnaris*. The *Flexor carpi ulnaris* occupies a small part of the posterior surface of the forearm, and is separated from the extensor and supinator group, which occupies the greater part of this surface, by the ulnar furrow, produced by the subcutaneous posterior border of the ulna. Its tendon can be perceived along the ulnar border of the front of the forearm, and is most marked when the hand is flexed and adducted. The deep muscles of the front of the forearm have no direct influence on surface form. The external group of muscles of the forearm, consisting of the extensors and supinators, occupy the outer and a considerable portion of the posterior surface of this region. It has a fusiform outline, which is altogether on a higher level than the pronator-flexor group. Its apex emerges from between the *Triceps* and *Brachialis anticus* muscles some distance above the elbow-joint, and acquires its greatest breadth opposite the external condyle, and thence gradually shades off into a flattened surface. About the middle of the forearm it divides into two longitudinal eminences which diverge from each other, leaving a triangular interval between them. The outer of these two groups of muscles consists of the *Supinator longus* and the *Extensor carpi radialis longior et brevior*, which form a longitudinal eminence descending from the external condylar ridge in the direction of the styloid process of the radius. The other and more posterior group consists of the *Extensor communis digitorum*, the *Extensor minimi digiti*, and the *Extensor carpi ulnaris*. It commences above as a tapering form at the external condyle of the humerus, and is separated behind at its upper part from the *Anconeus* by a well-marked furrow, and below, from the pronator-flexor mass, by the ulnar furrow. In the triangular interval left between these two groups the extensors of the thumb and index finger are seen. The only two muscles of this region which require special mention as independently influencing surface form are the *Supinator longus* and the *Anconeus*. The inner border of the *Supinator longus* forms the outer boundary of the triangular space at the bend of the elbow. It commences as a rounded border above the condyle, and is longer, less oblique, and more prominent than the inner boundary. Lower down, the muscle forms a full fleshy mass on the outer side of the upper part of the forearm, and below tapers into a tendon, which may be traced down to the styloid process of the radius. The *Anconeus* presents a well-marked and characteristic surface form in the shape of a triangular, slightly elevated surface, immediately external to the subcutaneous posterior surface of the olecranon, and differentiated from the common extensor group by a well-marked oblique longitudinal depression. The upper angle of the triangle corresponds to the external condyle, and is marked by a depression or dimple in this situation. In the interval caused by the divergence from each other of the two groups of muscles into which the extensor and supinator group is divided at the lower part of the forearm an oblique elongated eminence is seen, caused by the emergence of two of the extensors of the thumb from their deep origin at the back of the forearm. This eminence, full above and becoming flattened out and partially subdivided below, runs downward and outward over the back and outer surface of the radius to the outer side of the wrist-joint, where it forms a ridge, especially marked when the thumb is extended, which passes onward to the posterior aspect of the thumb. The tendons of most of the extensor muscles are to be seen and felt at the level of the wrist-joint. Most externally are the tendons of the *Extensor ossis metacarpi pollicis* and

the Extensor brevis pollicis, forming a vertical ridge over the outer side of the joint from the styloid process of the radius to the thumb. Internal to this is the oblique ridge produced by the tendon of the Extensor longus pollicis, very noticeable when the muscle is in action. The Extensor carpi radialis longior is scarcely to be felt, but the Extensor carpi radialis brevior can be distinctly perceived as a vertical ridge emerging from under the inner border of the tendon of the Extensor longus pollicis, when the hand is forcibly extended at the wrist. Internal to this, again, can be felt the tendons of the Extensor indicis, Extensor communis digitorum, and Extensor minimi digiti; the latter tendon being separated from those of the common extensor by a slight furrow. The muscles of the hand are principally concerned, as far as regards surface-form, in producing the thenar and hypothenar eminences, and individually are not to be distinguished, on the surface, from each other. The *Adductor transversus pollicis* is, however, an exception to this; its anterior border gives rise to a ridge across the web of skin connecting the thumb to the rest of the hand. The thenar eminence is much larger and rounder than the hypothenar one, which presents a longer and narrower eminence along the ulnar side of the hand. When the *Palmaris brevis* is in action it produces a wrinkling of the skin over the hypothenar eminence, and a deep dimple on the ulnar border of the hand. The anterior extremities of the *Lumbrical muscles* help to produce the soft eminences just behind the clefts of the fingers, separated from each other by depressions corresponding to the flexor tendons in their sheaths. Between the thenar and hypothenar eminences, at the wrist-joint, is a slight groove or depression, widening out as it approaches the fingers; beneath this we have the strong central part of the palmar fascia. Here we have some furrows, which are pretty constant in their arrangement, and bear some resemblance to the letter M. One of these furrows passes obliquely outward from the groove between the thenar and hypothenar regions near the wrist to the head of the metacarpal bone of the index finger. A second passes inward, with a slight inclination upward, from the termination of the first to the ulnar side of the hand. A third runs nearly parallel with the second and about three-quarters of an inch below it. Lastly, crossing these two latter furrows, is an oblique furrow parallel with the first. The skin of the palm of the hand differs considerably from that of the forearm. At the wrist it suddenly becomes hard and dense, and covered with a thick layer of cuticle. The skin in the thenar region presents these characteristics less than elsewhere. In spite of this hardness and density, the skin of the palm is exceedingly sensitive and very vascular. It is destitute of hair, and no sebaceous follicles have been found in this region. Over the fingers the skin again becomes thinner, especially at the flexures of the joints, and over the terminal phalanges it is thrown into numerous ridges in consequence of the arrangement of the papillæ in it. These ridges form, in different individuals, distinctive and permanent patterns, which may be used for purposes of identification. The superficial fascia in the palm is made up of dense fibro-fatty tissue. This tissue binds down the skin so firmly to the deep palmar fascia that very little movement is permitted between the two. On the back of the hand the *Dorsal interossei* produce elongated swellings between the metacarpal bones. The first dorsal interosseous (*Abductor indicis*), when the thumb is closely adducted to the hand, forms a prominent fusiform bulging; the other interossei are not so marked.

SURGICAL ANATOMY OF THE UPPER EXTREMITY.

The student, having completed the dissection of the muscles of the upper extremity, should consider the effects likely to be produced by the action of the various muscles in fracture of the bones.

In considering the actions of the various muscles upon fractures of the upper extremity, the most common forms of injury have been selected both for illustration and description.

Fracture of the *middle of the clavicle* (Fig. 246) is always attended with considerable displacement; the inner end of the outer fragment is displaced inward and backward, while the outer end of the same fragment is rotated forward. The whole outer fragment is somewhat depressed.

The displacement is produced as follows: *inward*, by the muscles passing from the chest to the outer fragment of the clavicle, to the scapula, and to the humerus, viz., the Subclavius and the Pectoralis minor, and, to a less extent, the Pectoralis major and the Latissimus dorsi; *backward*, in consequence of the rotation of the outer fragment. The Serratus magnus causes the scapula to rotate on the wall of the chest; this carries the acromion and outer end of the outer fragment of the clavicle forward and causes the piece of bone to rotate round a vertical axis through its centre, and so carries the inner end of the outer portion backward. The depression of the whole outer fragment is produced by the weight of the arm and by the contraction of the Deltoid. The outer end of the inner fragment appears to be elevated, the skin being drawn tensely over it; this is owing to the depression of the outer fragment, as the inner fragment is usually kept fixed by the costo-clavicular ligament and by the antagonism between the Sternomastoid and Pectoralis major muscles. But it may be raised by an unusually strong Sternomastoid, or by the inner end of the outer fragment getting below and behind it. The causes of displacement having been ascertained, it is easy to apply the appropriate treatment. The outer fragment is to be drawn outward, and, together with the scapula, raised upward to a level with the inner fragment, and retained in that position.

In fracture of the *acromial end of the clavicle*, between the conoid and trapezoid ligaments, only slight displacement occurs, as these ligaments, from their oblique insertion, serve to hold both portions of the bone in apposition. Fracture, also, of the *sternal end*, internal to the costo-clavicular ligament, is attended with only slight displacement, this ligament serving to retain the fragments in close apposition.

FIG. 246.—Fracture of the middle of the clavicle.

has remained intact, and has kept the separated fragment from displacement. In order to relax these muscles and replace the fragments in close apposition, the forearm should be flexed so as to relax the Biceps, and the arm drawn forward and inward across the chest, so as to relax the Coraco-brachialis; the humerus should then be pushed upward against the coraco-acromial ligament, and the arm retained in that position.

Fracture of the *surgical neck of the humerus* (Fig. 247) is very common, is attended with considerable displacement, and its appearances correspond somewhat with those of dislocation of the head of the humerus into the axilla. The upper fragment is slightly elevated under the coraco-acromial ligament by the muscles attached to the greater and lesser tuberosities; the lower fragment is drawn inward by the Pectoralis major, Latissimus dorsi, and Teres major; and the humerus is thrown obliquely outward from the side by the Deltoid, and occasionally elevated so as to cause the upper end of the lower fragment to project beneath and in front of the coraco-coid process. The deformity is reduced by fixing the shoulder, and drawing the arm outward and downward. To counteract the opposing muscles, and to keep the fragments in position, a small conical-shaped pad should be placed in the axilla, and the arm bandaged to the side by a broad roller passed round the chest, in such a manner that the elbow is carried slightly forward, so as to throw the upper end of the lower fragment backward and outward toward the head of the bone. The whole is then covered with a carefully moulded gutta-percha or poroplastic shoulder cap.

FIG. 247.—Fracture of the surgical neck of the humerus.

In fracture of the *shaft of the humerus* below the insertion of the Pectoralis major, Latissimus dorsi, and Teres major, and above the insertion of the Deltoid, there is also considerable deformity, the upper fragment being drawn inward by the first-mentioned muscles, and the lower fragment upward and outward by the Deltoid, producing shortening of the limb and a considerable prominence at the seat of fracture, from the fractured ends of the bone riding over one another, especially if the fracture takes place in an oblique direction. The fragments may be brought into apposition by extension from the elbow, and retained in that position by adopting the same means as in the preceding injury.

In fractures of the *shaft of the humerus* immediately below the insertion of the Deltoid, the amount of deformity depends greatly upon the direction of the fracture. If it occurs in a transverse direction, only slight displacement takes place, the upper fragment being drawn a little forward; but in oblique fracture the combined actions of the Biceps and Brachialis anticus muscles in front and the Triceps behind draw upward the lower fragment, causing it to glide over the upper fragment, either backward or forward, accord-

ing to the direction of the fracture. Simple extension reduces the deformity, and the application of a shoulder cap and splints to the arm will retain the fragments in apposition. Care should be taken not to raise the elbow, but the forearm and hand may be supported in a sling.

Fracture of the *humerus* (Fig. 248) immediately above the condyles deserves very attentive consideration, as the general appearances correspond somewhat with those produced by separation of the epiphysis of the humerus, and with those of dislocation of the radius and ulna backward. If the direction of the fracture is oblique from above, downward and forward, the lower fragment is drawn upward by the *Brachialis anticus* and *Biceps* in front and the *Triceps* behind; and at the same time is drawn backward behind the upper fragment of the *Triceps*. This injury may be diagnosed from dislocation by the increased mobility in fracture, the existence of crepitus, and the fact of the deformity being remedied by extension, on the discontinuance of which it is reproduced. The age of the patient is of importance in distinguishing this form of injury from separation of the epiphysis. If fracture occurs in the opposite direction to that shown in Fig. 248, the lower fragment is drawn upward and forward, causing a considerable prominence in front, and the upper fragment projects backward beneath the tendon of the *Triceps* muscle.

Fracture of the *olecranon process* (Fig. 249) is a frequent accident. The detached fragment is displaced upward, by the action of the *Triceps* muscle, from half an inch to two inches; the

FIG. 248.—Fracture of the humerus above the condyles.

FIG. 249.—Fracture of the olecranon.

prominence of the elbow is consequently lost, and a deep hollow is felt at the back part of the joint, which is much increased on flexing the limb. The patient at the same time loses, more or less, the power of extending the forearm. The treatment consists in relaxing the *Triceps* by extending the limb, and retaining it in the extended position by means of a long straight splint applied to the front of the arm; the fragments are thus brought into close apposition, and may be further approximated by drawing down the upper fragment. Union is generally ligamentous.

Fracture of the *neck of the radius* is an exceedingly rare accident, and is generally caused by direct violence. Its diagnosis is somewhat obscure, on account of the slight deformity visible, the injured part being surrounded by a large number of muscles; but the movements of pronation and supination are entirely lost. The upper fragment is drawn outward by the *Supinator brevis*, its extent of displacement being limited by the attachment of the orbicular ligament. The lower fragment is drawn forward and slightly upward by the *Biceps*, and inward by the *Pronator radii teres*, its displacement forward and upward being counteracted in some degree by the *Supinator brevis*. The treatment essentially consists in relaxing the *Biceps*, *Supinator brevis*, and *Pronator radii teres* muscles by flexing the forearm, and placing it in a position midway between pronation and supination, extension having been previously made so as to bring the parts in apposition.

In fracture of the *radius* below the insertion of the *Biceps*, but above the insertion of the *Pronator radii teres*, the upper fragment is strongly supinated by the *Biceps* and *Supinator brevis*, and at the same time drawn forward and flexed by the *Biceps*; the lower fragment is pronated and drawn inward toward the ulna by the pronators. Thus there is extreme displacement with very little deformity. In treating such a fracture the arm must be put up in

a position of supination, otherwise union will take place with great impairment of the movements of the hand. In fractures of the radius below the insertion of the Pronator radii teres

FIG. 250.—Fracture of the shaft of the radius.

forearm should be bent, and the limb placed in a position midway between pronation and supination; the fracture is then easily reduced by extension from the wrist and elbow: well-padded splints should be applied on both sides of the forearm from the elbow to the wrist; the hand being allowed to fall, will, by its own weight, counteract the action of the Pronator quadratus and Supinator longus, and elevate the lower fragment to the level of the upper one.

In fracture of the *shaft of the ulna* the upper fragment retains its usual position, but the lower fragment is drawn outward toward the radius by the Pronator quadratus, producing a well-marked depression at the seat of fracture and some fulness on the dorsal and palmar surfaces of the forearm. The fracture is easily reduced by extension from the wrist and forearm. The forearm should be flexed, and placed in a position midway between pronation and supination, and well-padded splints applied from the elbow to the ends of the fingers.

In fracture of the *shafts of the radius and ulna together* the lower fragments are drawn upward, sometimes forward, sometimes backward, according to the direction of the fracture, by the combined actions of the Flexor and Extensor muscles, producing a degree of fulness on the dorsal or palmar surface of the forearm; at the same time the two fragments are drawn into contact by the Pronator quadratus, the radius being in a state of pronation: the upper fragment of the radius is drawn upward and inward by the Biceps and Pronator radii teres to a higher level than the ulna; the upper portion of the ulna is slightly elevated by the Brachialis anticus. The fracture may be reduced by extension from the wrist and elbow, and the forearm should be placed in the same position as in fracture of the ulna.

In fracture of the *lower end of the radius* (Fig. 251) the displacement which is produced is very considerable, and bears some resemblance to dislocation of the carpus backward, from which it should be carefully distinguished. The lower fragment is displaced backward and upward, but this displacement is probably due to the force of the blow driving the portion of the bone into this position and not to any muscular influence. The upper fragment projects forward, often lacerating the substance of the Pronator quadratus, and is drawn by this muscle into close contact with the lower end of the ulna, causing a projection on the anterior surface of

FIG. 251.—Fracture of the lower end of the radius.

the forearm, immediately above the carpus, from the flexor tendons being thrust forward. This fracture may be distinguished from dislocation by the deformity being removed on making sufficient extension, when crepitus may be occasionally detected; at the same time, on extension being discontinued, the parts immediately resume their deformed appearance (see also page 128). The age of the patient will also assist in determining whether the injury is fracture or separation of the epiphysis. The treatment consists in flexing the forearm, and making powerful extension from the wrist and elbow, depressing at the same time the radial side of the hand, and retaining the parts in that position by well-padded *pistol-shaped* splints.

MUSCLES AND FASCIÆ OF THE LOWER EXTREMITY.

The Muscles of the Lower Extremity are subdivided into groups corresponding with the different regions of the limb.

I. ILIAC REGION.

Psoas magnus.
Psoas parvus.
Iliacus.

Extensor proprius hallucis.
Extensor longus digitorum.
Peroneus tertius.

II. THIGH.**1. Anterior Femoral Region.**

Tensor fasciæ femoris.
Sartorius.
Rectus.
Vastus externus.
Vastus internus.
Crureus.
Subcrureus.

Quadriceps
extensor

2. Internal Femoral Region.

Gracilis.
Pectineus.
Adductor longus.
Adductor brevis.
Adductor magnus.

3. Gluteal Region.

Gluteus maximus.
Gluteus medius.
Gluteus minimus.
Pyriformis.
Obturator internus.
Gemellus superior.
Gemellus inferior.
Quadratus femoris.
Obturator externus.

4. Posterior Femoral Region.

Biceps.
Semitendinosus.
Semimembranosus.

III. LEG.**5. Anterior Tibio-fibular Region.**

Tibialis anticus.

6. Posterior Tibio-fibular Region.**Superficial Layer.**

Gastrocnemius.
Soleus.
Plantaris.

Deep Layer.

Popliteus.
Flexor longus hallucis.
Flexor longus digitorum.
Tibialis posticus.

7. Fibular Region.

Peroneus longus.
Peroneus brevis.

IV. FOOT.**8. Dorsal Region.**

Extensor brevis digitorum.

9. Plantar Region.**First Layer.**

Abductor hallucis.
Flexor brevis digitorum.
Abductor minimi digiti.

Second Layer.

Flexor accessorius.
Lumbricales.

Third Layer.

Flexor brevis hallucis.
Adductor obliquus hallucis.
Flexor brevis minimi digiti.
Adductor transversus hallucis.

Fourth Layer.

The Interossei.

I. MUSCLES AND FASCIÆ OF THE ILIAC REGION.

Psoas magnus.

Psoas parvus.

Iliacus.

Dissection.—No detailed description is required for the dissection of these muscles. On the removal of the viscera from the abdomen they are exposed, covered by the peritoneum and a thin layer of fascia, the iliac fascia.

The *iliac fascia*¹ is the aponeurotic layer which lines the back part of the abdominal cavity, and covers the Psoas and Iliacus muscles throughout their whole

¹The student must not confound this fascia with the *iliac portion of the fascia lata* (see p. 420).

extent. It is thin above, and becomes gradually thicker below as it approaches the crural arch.

The *portion covering the Psoas* is attached, above, to the ligamentum arcuatum internum; internally, by a series of arched processes to the intervertebral substances and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum, the intervals so left, opposite the constricted portions of the bodies, transmitting the lumbar arteries and veins and filaments of the sympathetic cord. Externally, above the crest of the ilium, this portion of the iliac fascia is continuous with the anterior lamella of the lumbar fascia (see page 342), but below the crest of the ilium it is continuous with the fascia covering the Iliacus.

The *portion investing the Iliacus* is connected externally to the whole length of the inner border of the crest of the ilium, and internally to the brim of the true pelvis, where it is continuous with the periosteum; and at the ilio-pectineal eminence it receives the tendon of insertion of the Psoas parvus, when that muscle exists. External to the femoral vessels, this fascia is intimately connected to the posterior margin of Poupart's ligament, and is continuous with the fascia transversalis. Immediately to the outer side of the femoral vessels the fascia iliaca is prolonged backward and inward from Poupart's ligament as a band, the *ilio-pectineal ligament*, which is attached to the ilio-pectineal eminence. This ligament divides the space between Poupart's ligament and the innominate bone into two parts, the inner of which transmits the femoral vessels, the outer the ilio-psoas and the anterior crural nerve (Fig. 166). Internal to the vessels the iliac fascia is attached to the ilio-pectineal line behind the conjoined tendon, where it is again continuous with the transversalis fascia; and, corresponding to the point where the femoral vessels pass into the thigh, this fascia descends behind them, forming the posterior wall of the femoral sheath. This portion of the iliac fascia which passes behind the femoral vessels is also attached to the ilio-pectineal line beyond the limits of the attachment of the conjoined tendon; at this part it is continuous with the pubic portion of the fascia lata of the thigh. The external iliac vessels lie in front of the iliac fascia, but all the branches of the lumbar plexus behind it; it is separated from the peritoneum by a quantity of loose areolar tissue.

The *Psoas magnus* (Fig. 253) is a long fusiform muscle placed on the side of the lumbar region of the spine and margin of the pelvis. It arises from the front of the bases and lower borders of the transverse processes of the lumbar vertebræ by five fleshy slips; also from the sides of the bodies and the corresponding intervertebral substances of the last dorsal and all the lumbar vertebræ. The muscle is connected to the bodies of the vertebræ by five slips; each slip is attached to the upper and lower margins of two vertebræ, and to the intervertebral substance between them, the slips themselves being connected by the tendinous arches which extend across the constricted part of the bodies, and beneath which pass the lumbar arteries and veins and filaments of the sympathetic cord. These tendinous arches also give origin to muscular fibres, and protect the blood-vessels and nerves from pressure during the action of the muscle. The first slip is attached to the contiguous margins of the last dorsal and first lumbar vertebræ; the last to the contiguous margins of the fourth and fifth lumbar vertebræ, and to the intervertebral substance. From these points the muscle passes down across the brim of the pelvis, and, diminishing gradually in size, passes beneath Poupart's ligament, and terminates in a tendon which, after receiving nearly the whole of the fibres of the Iliacus, is inserted into the lesser trochanter of the femur.

Relations.—In the lumbar region: by its *anterior surface*, which is placed behind the peritoneum, with the iliac fascia, the ligamentum arcuatum internum, the kidney, Psoas parvus, renal vessels, ureter, spermatic vessels, genito-crural nerve, and the colon; by its *posterior surface*, with the transverse processes of the lumbar vertebræ and the Quadratus lumborum, from which it is separated by the anterior lamella of the lumbar fascia. The lumbar plexus is situated in the posterior part of the substance of the muscle. By its *inner side* the muscle is in relation with the bodies of the lumbar vertebræ, the lumbar arteries, the ganglia

of the sympathetic nerve, and their branches of communication with the spinal nerves; the lumbar glands; the vena cava inferior on the right and the aorta on the left side, and along the brim of the pelvis with the external iliac artery. In the thigh it is in relation, in front, with the fascia lata; behind, with the capsular ligament of the hip, from which it is separated by a synovial bursa, which frequently communicates with the cavity of the joint through an opening of variable size; by its *inner border*, with the Pectineus and internal circumflex artery, and also with the femoral artery, which slightly overlaps it: by its *outer border*, with the anterior crural nerve and Iliacus muscle.

The *Psoas parvus* is a long slender muscle placed in front of the *Psoas magnus*. It arises from the sides of the bodies of the last dorsal and first lumbar vertebræ and from the intervertebral substance between them. It forms a small flat muscular bundle, which terminates in a long flat tendon inserted into the ilio-pectineal eminence, and, by its outer border, into the iliac fascia. This muscle is often absent, and, according to Cruveilhier, sometimes double.

Relations.—It is covered by the peritoneum, and, at its origin, by the ligamentum arcuatum internum; it rests on the *Psoas magnus*.

The *Iliacus* is a flat, triangular muscle which fills up the whole of the iliac fossa. It arises from the upper two-thirds of this fossa and from the inner margin of the crest of the ilium; behind, from the ilio-lumbar ligament and base of the sacrum; in front, from the anterior superior and anterior inferior spinous processes of the ilium, from the notch between them, and by a few fibres from the capsule of the hip-joint. The fibres converge to be inserted into the outer side of the tendon of the *Psoas*, some of them being prolonged on to the shaft of the femur for about an inch below and in front of the lesser trochanter.¹

Relations.—*Within the abdomen*: by its *anterior surface*, with the iliac fascia, which separates the muscle from the peritoneum, and with the external cutaneous nerve; on the right side, with the cæcum; on the left side, with the sigmoid flexure of the colon; by its *posterior surface*, with the iliac fossa; by its *inner border*, with the *Psoas magnus* and anterior crural nerve. In the thigh, it is in relation, by its *anterior surface*, with the fascia lata, Rectus, Sartorius, and profunda femoris artery; behind, with the capsule of the hip-joint, a synovial bursa common to it and the *Psoas magnus* being interposed.

Nerves.—The *Psoas magnus* is supplied by the anterior branches of the second and third lumbar nerves; the *Psoas parvus*, when it exists, is supplied by the anterior branch of the first lumbar nerve; and the *Iliacus* by the anterior branches of the second and third lumbar nerves through the anterior crural.

Actions.—The *Psoas* and *Iliacus* muscles, acting from above, flex the thigh upon the pelvis. Acting from below, the femur being fixed, the muscles of both sides bend the lumbar portion of the spine and pelvis forward. They also serve to maintain the erect position, by supporting the spine and pelvis upon the femur, and assist in raising the trunk when the body is in the recumbent posture.

The *Psoas parvus* is a tensor of the iliac fascia.

Surgical Anatomy.—In the iliac fascia there is no definite septum between the portions of fascia covering the *Psoas* and *Iliacus* respectively, and the fascia is only connected to the subjacent muscles by a quantity of loose connective tissue. When abscess forms beneath this fascia, as it is very apt to do, the matter is contained in an osseo-fibrous cavity which is closed on all sides within the abdomen, and is open only at its lower part, where the fascia is prolonged over the muscle into the thigh.

Abscess within the sheath of the *Psoas* muscle (*Psoas abscess*) is generally due to tubercular caries of the bodies of the lower dorsal and lumbar vertebræ. When the disease is in the dorsal region, the matter tracts down the posterior mediastinum, in front of the bodies of the vertebræ, and, passing beneath the ligamentum arcuatum internum, enters the sheath of the *Psoas* muscle, down which it passes as far as the pelvic brim; it then gets beneath the iliac portion of the fascia and fills up the iliac fossa. In consequence of the attachment of the fascia to the pelvic brim, it rarely finds its way into the pelvis, but passes by a narrow opening under Poupart's ligament

¹ The *Psoas* and *Iliacus* are sometimes regarded as a single muscle, the *Ilio-psoas*, having two heads of origin and a single insertion.

into the thigh, to the outer side of the femoral vessels. It thus follows that a Psoas abscess may be described as consisting of four parts: (1) a somewhat narrow channel at its upper part, in the Psoas sheath; (2) a dilated sac in the iliac fossa; (3) a constricted neck under Poupart's ligament; and (4) a dilated sac in the upper part of the thigh. When the lumbar vertebræ are the seat of the disease, the matter finds its way directly into the substance of the muscle. The muscular fibres are destroyed, and the nervous cords contained in the abscess are isolated and exposed in its interior; the femoral vessels which lie in front of the fascia remain intact, and the peritoneum seldom becomes implicated. All Psoas abscesses do not, however, pursue this course: the matter may leave the muscle above the crest of the ilium, and, tracking backward, may point in the loin (*lumbar abscess*); or it may point above Poupart's ligament in the inguinal region; or it may follow the course of the iliac vessels into the pelvis, and, passing through the great sacro-sciatic notch, discharge itself on the back of the thigh; or it may open into the bladder or find its way into the perinæum.

II. MUSCLES AND FASCIÆ OF THE THIGH.

1. Anterior Femoral Region.

Tensor fasciæ femoris.	Quadriceps	{ Rectus. Vastus externus. Vastus internus. Crureus.
Sartorius.	extensor	
	Subcrureus.	

Dissection.—To expose the muscles and fasciæ in this region, make an incision along Poupart's ligament, from the anterior superior spine of the ilium to the spine of the os pubis; a vertical incision from the centre of this, along the middle of the thigh to below the knee-joint; and a transverse incision from the inner to the outer side of the leg, at the lower end of the vertical incision. The flaps of integument having been removed, the superficial and deep fasciæ should be examined. The more advanced student should commence the study of this region by an examination of the anatomy of femoral hernia and Scarpa's triangle, the incisions for the dissection of which are marked out in the figure 252.

The **superficial fascia** forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb: in the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these two layers, the superficial, is continuous above with the superficial fascia of the abdomen. The deep layer of the superficial fascia is a very thin, fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart's ligament. It is placed beneath the subcutaneous vessels and nerves and upon the surface of the fascia lata. It is intimately adherent to the fascia lata a little below Poupart's ligament. It covers the saphenous opening in the fascia lata, being closely united to its circumference, and is connected to the sheath of the femoral vessels, corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the *cribriform fascia*, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as part of the fascia lata, but is usually considered (as in this work) as belonging to the superficial fascia. It is not until the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. Mr. Callender, however, speaks of cases in which, probably as the result of pressure from enlarged inguinal lymphatic glands, the fascia has become atrophied, and a saphenous opening exists independent of dissection. A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings. A large subcutaneous bursa is found in the superficial fascia over the patella.

The **deep fascia** of the thigh is exposed on the removal of the superficial fascia,

and is named, from its great extent, the *fascia lata*; it forms a uniform investment for the whole of this region of the limb, but varies in thickness in different parts; thus, it is thicker in the upper and outer part of the thigh, where it receives a fibrous expansion from the Gluteus maximus muscle, and the Tensor fasciæ femoris is inserted between its layers: it is very thin behind, and at the upper and inner part where it covers the Adductor muscles, and again becomes stronger around the knee, receiving fibrous expansions from the tendon of the Biceps externally, and from the Sartorius internally, and Quadriceps extensor cruris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx; externally, to the crest of the ilium; in front, to Poupart's ligament and to the body of the os pubis; and internally, to the descending ramus of the os pubis, to the ramus and tuberosity of the ischium, and to the lower border of the great sacro-sciatic ligament. From its attachment to the crest of the ilium it passes down over the Gluteus medius muscle to the upper border of the Gluteus maximus, where it splits into two layers, one passing superficial to and the other beneath this muscle. At the lower border of the muscle the two layers reunite. Externally the fascia lata receives the greater part of the tendon of insertion of the Gluteus maximus, and becomes proportionately thickened. The portion of the fascia lata arising from the front part of the crest of the ilium, corresponding to the origin of the Tensor fasciæ femoris, passes down the outer side of the thigh as two layers, one superficial to and the other beneath this muscle; these at its lower end become blended together into a thick and strong band, having first received the insertion of the muscle. This band is continued downward, under the name of the *ilio-tibial band*, to be inserted into the external tuberosity of the tibia. Below, the fascia lata is attached to all the prominent points around the knee-joint—viz., the condyles of the femur, tuberosities of the tibia, and head of the fibula. On each side of the patella it is strengthened by transverse fibres given off from the lower part of the Vasti muscles, which are attached to and support this bone. Of these the outer is the stronger, and is continuous with the ilio-tibial band. From the inner surface of the fascia lata are given off two strong intermuscular septa, which are attached to the whole length of the linea aspera and its prolongations above and below: the external and stronger one, which extends from the insertion of the Gluteus maximus to the outer condyle, separates the Vastus externus in front from the short head of the Biceps behind, and gives partial origin to these muscles; the inner one, the thinner of the two, separates the Vastus internus from the Adductor and Pectineus muscles. Besides these there are numerous smaller septa, separating the individual muscles and enclosing each in a distinct sheath. At the upper and inner part of the thigh, a little below Poupart's ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared off: it transmits the internal saphenous vein and other smaller vessels, and is termed the *saphenous opening*. In order more correctly to consider the mode of formation of this aperture, the fascia lata in this

FIG. 252.—Dissection of lower extremity. Front view.

FIG. 253.—Muscles of the iliac and anterior femoral region.

part of the thigh is described as consisting of two portions—an iliac portion and a pubic portion.

The *iliac portion* is all that part of the fascia lata on the outer side of the saphenous opening. It is attached, externally, to the crest of the ilium and its anterior superior spine, to the whole length of Poupart's ligament as far internally as the spine of the os pubis, and to the pectineal line in conjunction with Gimbernath's ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the *falciform process* or boundary (*superior cornu*) of the saphenous opening; this margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels: to its edge is attached the cribriform fascia; and, below, it is continuous with the pubic portion of the fascia lata.

The *pubic portion* is situated at the inner side of the saphenous opening: at the lower margin of this aperture it is continuous with the iliac portion; traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles, and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the iliac fascia. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels, and the pubic portion behind them, so that an apparent aperture exists between the two, through which the internal saphenous joins the femoral vein.¹

The fascia should now be removed from the surface of the muscles. This may be effected by pinching it up between the forceps, dividing it, and separating it from each muscle in the course of its fibres.

The *Tensor fasciæ femoris* arises from the anterior part of the outer lip of the crest of the ilium, and from the outer surface of the anterior superior spinous process, and part of the outer border of the notch below it, between the Gluteus medius and Sartorius, and from the surface of the fascia covering the Gluteus medius. It is inserted between two layers of the fascia lata, about one-fourth down the outer side of the thigh. From the point of insertion the fascia is continued downward to the external tuberosity of the tibia as a thickened band, the *ilio-tibial band*.

¹ These parts will be again more particularly described with the anatomy of Hernia.

Relations.—By its *superficial surface*, with the fascia lata and the integument; by its *deep surface*, with the Gluteus medius, Rectus femoris, Vastus externus, and the ascending branches of the external circumflex artery; by its *anterior border*, with the Sartorius, from which it is separated below by a triangular space, in which is seen the Rectus femoris; by its *posterior border*, with the Gluteus medius.

The **Sartorius**, the longest muscle in the body, is flat, narrow, and ribbon-like; it arises by tendinous fibres from the anterior superior spinous process of the ilium and the upper half of the notch below it, passes obliquely across the upper and anterior part of the thigh, from the outer to the inner side of the limb, then descends vertically, as far as the inner side of the knee, passing behind the inner condyle of the femur, and terminates in a tendon which, curving obliquely forward, expands into a broad aponeurosis, inserted, in front of the Gracilis and Semitendinosus, into the upper part of the inner surface of the shaft of the tibia, nearly as far forward as the crest. The upper part of the tendon is curved backward over the upper edge of the tendon of the Gracilis so as to be inserted behind it. An offset is derived from the upper margin of this aponeurosis, which blends with the fibrous capsule of the knee-joint, and another, given off from its lower border, blends with the fascia on the inner side of the leg.

The relations of this muscle to the femoral artery should be carefully examined, as it constitutes the chief guide in tying the vessel. In the upper third of the thigh it forms the outer side of a triangular space, *Scarpa's triangle*, the inner side of which is formed by the inner border of the Adductor longus, and the base, turned upward, by Poupart's ligament; the femoral artery passes perpendicularly through the middle of this space from its base to its apex. In the middle third of the thigh the femoral artery lies first along the inner border, and then behind the Sartorius.

Relations.—By its *superficial surface*, with the fascia lata and integument; by its *deep surface*, with the Rectus, Iliacus, Vastus internus, anterior crural nerve, sheath of the femoral vessels, Adductor longus, Adductor magnus, Gracilis, Semitendinosus, long saphenous nerve, and internal lateral ligament of the knee-joint.

The **Quadriceps extensor** includes the four remaining muscles on the front of the thigh. It is the great Extensor muscle of the leg, forming a large fleshy mass which covers the front and sides of the femur, being united below into a single tendon, attached to the patella, and above subdivided into separate portions, which have received distinct names. Of these, one occupying the middle of the thigh, connected above with the ilium, is called the *Rectus femoris*, from its straight course. The other divisions lie in immediate connection with the shaft of the femur, which they cover from the trochanters to the condyles. The portion on the outer side of the femur is termed the *Vastus externus*; that covering the inner side, the *Vastus internus*; and that covering the front of the femur, the *Crureus*.

The **Rectus femoris** is situated in the middle of the anterior region of the thigh; it is fusiform in shape, and its superficial fibres are arranged in a bipenniform manner, the deep fibres running straight down to the deep aponeurosis. It arises by two tendons: one, the anterior or straight, from the anterior inferior spinous process of the ilium; the other, the posterior or reflected tendon, from a groove above the brim of the acetabulum; the two unite at an acute angle and spread into an aponeurosis, which is prolonged downward on the anterior surface of the muscle and from which the muscular fibres arise.¹ The muscle terminates in a broad and thick aponeurosis, which occupies the lower two-thirds of its pos-

¹ Mr. W. R. Williams, in an interesting paper in the *Journ. of Anat. and Phys.*, vol. xiii. p. 204, points out that the reflected tendon is the real origin of the muscle, and is alone present in early fetal life. The direct tendon is merely an accessory band of condensed fascia. The paper will well repay perusal, though in some particulars I think the description in the text more generally accurate.—ED.

terior surface, and, gradually becoming narrowed into a flattened tendon, is inserted into the patella in common with the Vasti and Crureus.

Relations.—By its *superficial surface*, with the anterior fibres of the Gluteus minimus, the Tensor fasciæ femoris, the Sartorius, and the Iliacus; by its lower three-fourths, with the fascia lata. By its *posterior surface*, with the hip-joint, the external circumflex vessels, branches of the anterior crural nerve, and the Crureus and Vasti muscles.

The **Vastus externus** is the largest part of the Quadriceps extensor. It arises by a broad aponeurosis, which is attached to the upper half of the anterior intertrochanteric line, to the anterior and inferior borders of the root of the great trochanter, to the outer lip of the gluteal ridge, and to the upper half of the outer lip of the linea aspera: this aponeurosis covers the upper three-fourths of the muscle, and from its inner surface many fibres take origin. A few additional fibres arise from the tendon of the Gluteus maximus, and from the external intermuscular septum between the Vastus externus and short head of the Biceps. The fibres form a large fleshy mass, which is attached to a strong aponeurosis, placed on the under surface of the muscle at its lower part: this becomes contracted and thickened into a flat tendon, which is inserted into the outer border of the patella, blending with the great Extensor tendon, and giving an expansion to the capsule of the knee-joint.

Relations.—By its *superficial surface*, with the Rectus, the Tensor fasciæ femoris, the fascia lata, and the tendon of the Gluteus maximus, from which it is separated by a synovial bursa. By its *deep surface*, with the Crureus, some large branches of the external circumflex artery and anterior crural nerve being interposed.

The **Vastus internus** and **Crureus** appear to be inseparably united, but when the Rectus femoris has been reflected, a narrow interval will be observed extending upward from the inner border of the patella between the two muscles. Here they can be separated, and the separation should be continued upward as far as the lower part of the anterior intertrochanteric line, where, however, the two muscles are frequently continuous.

The **Vastus internus** arises from the lower half of the anterior intertrochanteric line, the spiral line, the inner lip of the linea aspera, the upper part of the internal supra-condylar line, and the tendon of the Adductor magnus and internal intermuscular septum. Its fibres are directed downward and forward, and are chiefly attached to an aponeurosis which lies on the deep surface of the muscle and is inserted into the inner border of the patella and the Quadriceps extensor tendon, an expansion being sent to the capsule of the knee-joint.

The **Crureus** arises from the front and outer aspect of the shaft of the femur in its upper two-thirds and from the lower part of the external intermuscular septum. Its fibres end in a superficial aponeurosis, which forms the deep part of the Quadriceps extensor tendon.

Relations.—The inner edge of the Crureus is in contact with the anterior edge of the Vastus internus, but when separated from each other, as directed above, the latter muscle is seen merely to overlap the inner aspect of the femoral shaft without taking any fibres of origin from it. The Vastus internus is partly covered by the Rectus and Sartorius, but where these separate near the knee it becomes superficial, and produces a well-marked prominence above the inner aspect of the knee. In the middle third of the thigh it forms the outer wall of Hunter's canal, which contains the femoral vessels and the long saphenous nerve—the roof of the canal being formed by a strong fascia which extends from the Vastus internus to the Adductores longus and magnus. The Crureus is almost completely hidden by the Rectus femoris and Vastus externus. The deep surface of the two muscles is in relation to the femur and Subcrureus muscle. A synovial bursa is situated between the femur and the portion of the Quadriceps extensor tendon above the patella; in the adult it communicates with the synovial cavity of the knee-joint.

The *tendons* of the different portions of the Quadriceps extensor unite at the

lower part of the thigh, so as to form a single strong tendon, which is inserted into the upper part of the patella, some few fibres passing over it to blend with the Ligamentum patellæ. More properly, the patella may be regarded as a sesamoid bone, developed in the tendon of the Quadriceps; and the Ligamentum patellæ, which is continued from the lower part of the patella to the tuberosity of the tibia, as the proper tendon of insertion of the muscle. A synovial bursa, the *post-patellar bursa*, is interposed between the tendon and the upper part of the tuberosity of the tibia; and another, the *pre-patellar bursa*, is placed over the patella itself. This latter bursa often becomes enlarged, constituting "house-maid's knee."

The *Subcrureus* is a small muscle, usually distinct from the *Crureus*, but occasionally blended with it, which arises from the anterior surface of the lower part of the shaft of the femur, and is inserted into the upper part of the *cul-de-sac* of the capsular ligament which projects upward beneath the Quadriceps for a variable distance. It sometimes consists of several separate muscular bundles.

Nerves.—The Tensor fasciæ femoris is supplied by the fourth and fifth lumbar and first sacral nerves through the superior gluteal nerve; the other muscles of this region, by the second, third, and fourth lumbar nerves, through branches of the anterior crural.

Actions.—The Tensor fasciæ femoris is a tensor of the fascia lata; continuing its action, the oblique direction of its fibres enables it to abduct and to rotate the thigh inward. In the erect posture, acting from below, it will serve to steady the pelvis upon the head of the femur, and by means of the ilio-tibial band it steadies the condyles of the femur on the articular surfaces of the tibia, and assists the Gluteus maximus in supporting the knee in the extended position. The Sartorius flexes the leg upon the thigh, and, continuing to act, flexes the thigh upon the pelvis; it next rotates the thigh outward. It was formerly supposed to adduct the thigh, so as to cross one leg over the other, and hence received its name of Sartorius, or tailor's muscle (*sartor*, a tailor), because it was supposed to assist in crossing the legs in the squatting position. When the knee is bent the Sartorius assists the Semitendinosus, Semimembranosus, and Popliteus in rotating the tibia inward. Taking its fixed point from the leg, it flexes the pelvis upon the thigh, and, if one muscle acts, assists in rotating the pelvis. The Quadriceps extensor extends the leg upon the thigh. The Rectus muscle assists the Psoas and Iliacus in supporting the pelvis and trunk upon the femur. It also assists in flexing the thigh on the pelvis, or if the thigh is fixed it will flex the pelvis. The Vastus internus draws the patella inward as well as upward.

Surgical Anatomy.—A few fibres of the Rectus muscle are liable to be ruptured from severe strain. This accident is especially liable to occur during the games of football and cricket, and is sometimes known as "cricket thigh." The patient experiences a sudden pain in the part, as if he had been struck, and the Rectus muscle stands out and is felt to be tense and rigid. The accident is often followed by considerable swelling from inflammatory effusion. Occasionally the Quadriceps extensor may be torn away from its insertion into the patella, or the tendon of the patella may be ruptured about an inch above the bone. This accident is caused in the same manner as fracture of the patella by muscular action is produced—viz. by a violent muscular effort to prevent falling whilst the knee is in a position of semiflexion. A distinct gap can be felt above the patella, and, owing to the retraction of the muscular fibres, union may fail to take place.

2. Internal Femoral Region.

Gracilis.

Adductor longus.

Pectineus.

Adductor brevis.

Adductor magnus.

Dissection.—These muscles are at once exposed by removing the fascia from the fore part and inner side of the thigh. The limb should be abducted, so as to render the muscles tense and easier of dissection.

The *Gracilis* (Figs. 253, 256) is the most superficial muscle on the inner side of the thigh. It is thin and flattened, broad above, narrowing and tapering below. It arises by a thin aponeurosis from the lower half of the margin of the symphysis and the anterior half of the pubic arch. The fibres pass vertically downward, and

terminate in a rounded tendon which passes behind the internal condyle of the femur, and, curving round the inner tuberosity of the tibia, becomes flattened, and

is inserted into the upper part of the inner surface of the shaft of the tibia, below the tuberosity. A few of the fibres of the lower part of the tendon are prolonged into the deep fascia of the leg. The tendon of this muscle is situated immediately above that of the Semitendinosus, and its upper edge is overlapped by the tendon of the Sartorius, with which it is in part blended. As it passes across the internal lateral ligament of the knee-joint it is separated from it by a synovial bursa common to it and the Semitendinosus muscle.

Relations.—By its *superficial surface*, with the fascia lata and the Sartorius below: the internal saphenous vein crosses it obliquely near its lower part, lying superficial to the fascia lata; the internal saphenous nerve emerges between its tendon and that of the Sartorius; by its *deep surface*, with the Adductor brevis and the Adductor magnus and the internal lateral ligament of the knee-joint.

The Pectineus (Fig. 253) is a flat, quadrangular muscle, situated at the anterior part of the upper and inner aspect of the thigh. It arises from the linea ilio-pectinea, and to a slight extent from the surface of the bone in front of it between the pectineal eminence and spine of the os pubis, and from the fascia covering the anterior surface of the muscle; the fibres pass downward, backward, and outward, to be inserted into a rough line leading from the lesser trochanter to the linea aspera.

Relations.—By its *anterior surface*, with the pubic portion of the fascia lata, which separates it from the femoral vessels and internal saphenous vein; by its *posterior surface*, with the capsular ligament of the hip-joint, the Adductor brevis and Obturator externus muscles, the obturator vessels and nerve being interposed; by its *outer border*, with the Psoas, a cellular interval separating them, through which pass the internal circumflex vessels; by its *inner border*, with the margin of the Adductor longus.

The Adductor longus, the most superficial of the three Adductors, is a flat triangular muscle lying on the same plane as the Pectineus. It arises, by a flat narrow tendon, from the front of the os pubis, at the angle of junction of the crest with the

symphysis; and soon expands into a broad fleshy belly, which, passing downward, backward, and outward, is inserted, by an aponeurosis, into the linea

FIG. 254. Deep muscles of the internal femoral region.

aspera, between the Vastus internus and the Adductor magnus, with both of which it is usually blended.

Relations.—By its *anterior surface*, with the fascia lata, the Sartorius, and, near its insertion, with the femoral artery and vein; by its *posterior surface*, with the Adductor brevis and magnus, the anterior branches of the obturator nerve, and with the profunda artery and vein near its insertion; by its *outer border*, with the Pectineus; by its *inner border*, with the Gracilis.

The Pectineus and Adductor longus should now be divided near their origin, and turned downward, when the Adductor brevis and Obturator externus will be exposed.

The **Adductor brevis** is situated immediately behind the two preceding muscles. It is somewhat triangular in form, and arises by a narrow origin from the outer surface of the body and descending ramus of the os pubis, between the Gracilis and Obturator externus. Its fibres, passing backward, outward, and downward, are inserted, by an aponeurosis, into the lower part of the line leading from the lesser trochanter to the linea aspera and the upper part of the same line, immediately behind the Pectineus and upper part of the Adductor longus.

Relations.—By its *anterior surface*, with the Pectineus, Adductor longus, profunda femoris artery, and anterior branches of the obturator nerve; by its *posterior surface*, with the Adductor magnus and posterior branch of the obturator nerve; by its *outer border*, with the internal circumflex artery, the Obturator externus, and conjoined tendon of the Psoas and Iliacus; by its *inner border*, with the Gracilis and Adductor magnus. This muscle is pierced, near its insertion, by the second or first and second perforating branches of the profunda femoris artery.

The Adductor brevis should now be cut away near its origin, and turned outward, when the entire extent of the Adductor magnus will be exposed.

The **Adductor magnus** is a large triangular muscle forming a septum between the muscles on the inner and those on the back of the thigh. It arises from a small part of the descending ramus of the os pubis, from the ramus of the ischium, and from the outer margin of the inferior part of the tuberosity of the ischium. Those fibres which arise from the ramus of the os pubis are very short, horizontal in direction, and are inserted into the rough line leading from the great trochanter to the linea aspera, internal to the Gluteus maximus; those from the ramus of the ischium are directed downward and outward with different degrees of obliquity, to be inserted, by means of a broad aponeurosis, into the linea aspera and the upper part of its internal prolongation below. The internal portion of the muscle, consisting principally of those fibres which arise from the tuberosity of the ischium, forms a thick fleshy mass consisting of coarse bundles which descend almost vertically, and terminate about the lower third of the thigh in a rounded tendon, which is inserted into the Adductor tubercle on the inner condyle of the femur, being connected by a fibrous expansion to the line leading upward from the tubercle to the linea aspera. Between the two portions of the muscle an interval is left, tendinous in front, fleshy behind, for the passage of the femoral vessels into the popliteal space. The external portion of the muscle at its attachment to the femur presents three or four osseo-aponeurotic openings, formed by tendinous arches attached to the bone, from which muscular fibres arise. The three superior of these apertures are for the three perforating arteries, and the fourth, when it exists, for the terminal branch of the profunda.

Relations.—By its *anterior surface*, with the Pectineus, Adductor brevis, Adductor longus, and the femoral and profunda vessels and obturator nerve; by its *posterior surface*, with the great sciatic nerve, the Gluteus maximus, Biceps, Semitendinosus, and Semimembranosus. By its *superior or shortest border* it lies parallel with the Quadratus femoris, the internal circumflex artery passing between them; by its *internal or longest border*, with the Gracilis, Sartorius, and fascia lata; by its *external or attached border* it is inserted into the femur behind the Adductor brevis and Adductor longus, which separate it from the Vastus internus,

and in front of the *Gluteus maximus* and short head of the *Biceps*, which separate it from the *Vastus externus*.

Nerves.—The three Adductor muscles and the *Gracilis* are supplied by the third and fourth lumbar nerves through the obturator nerve; the *Adductor magnus* receiving an additional branch from the sacral plexus through the great sciatic. The *Pectineus* is supplied by the second, third, and fourth lumbar nerves through the anterior crural, and by the accessory obturator, from the third lumbar, when it exists. Occasionally it receives a branch from the obturator nerve.¹

Actions.—The *Pectineus* and three Adductors adduct the thigh powerfully; they are especially used in horse exercise, the flanks of the horse being grasped between the knees by the actions of these muscles. In consequence of the obliquity of their insertion into the *linea aspera* they rotate the thigh outward, assisting the external Rotators, and when the limb has been abducted they draw it inward, carrying the thigh across that of the opposite side. The *Pectineus* and *Adductor brevis* and *longus* assist the *Psoas* and *Iliacus* in flexing the thigh upon the pelvis. In progression, also, all these muscles assist in drawing forward the hinder limb. The *Gracilis* assists the *Sartorius* in flexing the leg and rotating it inward; it is also an adductor of the thigh. If the lower extremities are fixed, these muscles may take their fixed point from below and act upon the pelvis, serving to maintain the body in an erect posture, or, if their action is continued, to flex the pelvis forward upon the femur.

Surgical Anatomy.—The *Adductor longus* is liable to be severely strained in those who ride much on horseback, or its tendon to be ruptured by suddenly gripping the saddle. And, occasionally, especially in cavalry soldiers, the tendon may become ossified, constituting the "rider's bone."

THE HIP.

3. Gluteal Region.

<i>Gluteus maximus.</i>	<i>Obturator internus.</i>
<i>Gluteus medius.</i>	<i>Gemellus superior.</i>
<i>Gluteus minimus.</i>	<i>Gemellus inferior.</i>
<i>Pyriformis.</i>	<i>Quadratus femoris.</i>
<i>Obturator externus.</i>	

Dissection (Fig. 255).—The subject should be turned on its face, a block placed beneath the pelvis to make the buttocks tense, and the limbs allowed to hang over the end of the table, with the foot inverted and the thigh abducted. Make an incision through the integument along the crest of the ilium to the middle of the sacrum, and thence downward to the tip of the coccyx, and carry a second incision from that point obliquely downward and outward to the outer side of the thigh, four inches below the great trochanter. The portion of integument included between these incisions is to be removed in the direction shown in the figure.

The *Gluteus maximus* (Fig. 256), the most superficial muscle in the gluteal region, is a very broad and thick, fleshy mass of a quadrilateral shape, which forms the prominence of the nates. Its large size is one of the most characteristic points in the muscular system in man, connected as it is with the power he has of maintaining the trunk in the erect posture. In structure the muscle is remarkably coarse, being made up of muscular fasciculi lying parallel with one another, and collected together into large bundles, separated by deep cellular intervals. It arises from the superior curved line of the ilium and the portion of bone, including the crest, immediately above and behind it; from the posterior surface of the lower part of the sacrum, the side of the coccyx, the aponeurosis of the *Erector spinæ* muscle, the great sacro-sciatic ligament, and the fascia covering the *Gluteus medius*. The fibres are directed obliquely downward and outward; those forming the upper and larger portion of the muscle, together with the *superficial* fibres of the lower

¹ Professor Paterson describes the *Pectineus* as consisting of two incompletely separated strata, of which the outer or dorsal stratum, which is constant, is supplied by the anterior crural nerve, or in its absence by the accessory obturator, with which it is intimately related; while the inner or ventral stratum, when present, is supplied by the obturator nerve.—*Journal of Anatomy and Physiology*, vol. xxvi, p. 43.

portion, terminate in a thick tendinous lamina, which passes across the great trochanter and is inserted into the fascia lata covering the outer side of the thigh; the deeper fibres of the lower portion of the muscle are inserted into the rough line leading from the great trochanter to the linea aspera between the Vastus externus and Adductor magnus.

Three *synovial bursæ* are usually found in relation with this muscle. One of these, of large size, and generally multilocular, separates it from the great trochanter. A second, often wanting, is situated on the tuberosity of the ischium. A third is found between the tendon of this muscle and the Vastus externus.

Relations.—By its *superficial surface*, with a thin fascia, which separates it from the subcutaneous tissue; by its *deep surface*, from above downward, with the ilium, sacrum, coccyx, and great sacro-sciatic ligament, part of the Gluteus medius, Piriformis, Gemelli, Obturator internus, Quadratus femoris, the tuberosity of the ischium, great trochanter, the origin of the Biceps, Semitendinosus, Semimembranosus, and Adductor magnus muscles. The superficial part of the gluteal artery reaches the deep surface of the muscle by passing between the Piriformis and the Gluteus medius; the sciatic and internal pudic vessels and nerves and muscular branches from the sacral plexus issue from the pelvis below the Piriformis. The first perforating artery and the terminal branches of the internal circumflex artery are also found under cover of the muscle. Its *upper border* is thin, and connected with the Gluteus medius by the fascia lata. Its *lower border* is free and prominent.

Dissection.—Divide the Gluteus maximus near its origin by a vertical incision carried from its upper to its lower border; a cellular interval will be exposed, separating it from the Gluteus medius and External rotator muscles beneath. The upper portion of the muscle is to be altogether detached, and the lower portion turned outward; the loose areolar tissue filling up the interspace between the trochanter major and tuberosity of the ischium being removed, the parts already enumerated as exposed by the removal of this muscle will be seen.

The **Gluteus medius** is a broad, thick, radiated muscle, situated on the outer surface of the pelvis. Its posterior third is covered by the Gluteus maximus; its anterior two-thirds by the fascia lata, which separates it from the integument. It arises from the outer surface of the ilium, between the superior and middle curved lines, and from the outer lip of that portion of the crest which is between them; it also arises from the dense fascia (Gluteal aponeurosis) covering its outer surface. The fibres converge to a strong flattened tendon which is inserted into the oblique line which traverses the outer surface of the great trochanter. A synovial bursa separates the tendon of the muscle from the surface of the trochanter in front of its insertion.

Relations.—By its *superficial surface*, with the Gluteus maximus behind, the Tensor fasciæ femoris and deep fascia in front; by its *deep surface*, with the Gluteus minimus and the gluteal vessels and superior gluteal nerve. Its *anterior border* is blended with the Gluteus minimus. Its *posterior border* lies parallel with the Piriformis, the gluteal vessels intervening.

FIG. 255.—Dissection of lower extremity. Posterior view.

This muscle should now be divided near its insertion and turned upward, when the Gluteus minimus will be exposed.

The **Gluteus minimus**, the smallest of the three Glutei, is placed immediately beneath the preceding. It is fan-shaped, arising from the outer surface of the ilium, between the middle and inferior curved lines, and behind, from the margin of the great sacro-sciatic notch; the fibres converge to the deep surface of a radiated aponeurosis, which, terminating in a tendon, is inserted into an impression on the anterior border of the great trochanter. A synovial bursa is interposed between the tendon and the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus medius and the gluteal vessels and superior gluteal nerve; by its *deep surface*, with the ilium, the reflected tendon of the Rectus femoris, and capsular ligament of the hip-joint. Its *anterior margin* is blended with the Gluteus medius; its *posterior margin* is in contact and sometimes joined with the tendon of the Piriformis.

The **Piriformis** is a flat muscle, pyramidal in shape, lying almost parallel with the posterior margin of the Gluteus medius. It is situated partly within the pelvis at its posterior part and partly at the back of the hip-joint. It arises from the front of the sacrum by three fleshy digitations attached to the portions of bone between the first, second, third, and fourth anterior sacral foramina, and also from the groove leading from the foramina: a few fibres also arise from the margin of the great sacro-sciatic foramen and from the anterior surface of the great sacro-sciatic ligament. The muscle passes out of the pelvis through the great sacro-sciatic foramen, the upper part of which it fills, and is inserted by a rounded tendon into the upper border of the great tro-

FIG. 256.—Muscles of the hip and thigh.

chanter, behind, but often partly blended with, the tendon of the Obturator internus and Gemelli muscles.

Relations.—By its *anterior surface, within the pelvis*, with the Rectum (especially on the left side), the sacral plexus of nerves, and the branches of the internal iliac vessels; *external to the pelvis*, with the posterior surface of the ischium and capsular ligament of the hip-joint; by its *posterior surface, within the pelvis*, with the sacrum, and *external to it*, with the Gluteus maximus; by its *upper border*, with the Gluteus medius, from which it is separated by the gluteal vessels and superior gluteal nerve; by its *lower border*, with the Gemellus superior and Coccygeus, the sciatic vessels and nerves, the internal pudic vessels and nerve, and muscular branches from the sacral plexus, passing from the pelvis in the interval between the two muscles.

The **Obturator membrane** (Fig. 166) is a thin layer of interlacing fibres which closes the obturator foramen. It is attached, externally, to the margin of the foramen; internally, to the posterior surface of the ischio-pubic ramus, below and internal to the margin of the foramen. It is occasionally incomplete, and presents at its upper and outer part a small canal, which is bounded below by a thickened band of fibres, for the passage of the obturator vessels and nerve. Both obturator muscles are connected with this membrane.

Dissection.—The next muscle, as well as the origin of the Piriformis, can only be seen when the pelvis is divided and the viscera removed.

The **Obturator internus**, like the preceding muscle, is situated partly within the cavity of the pelvis, and partly at the back of the hip-joint. It arises from the inner surface of the anterior and external wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the descending ramus of the os pubis and the ramus of the ischium, and at the side to the inner surface of the innominate bone below and behind the pelvic brim, reaching from the upper part of the great sacro-sciatic foramen above and behind to the thyroid foramen below and in front. It also arises from the inner surface of the obturator membrane except at its posterior part, from the tendinous arch which completes the canal for the passage of the obturator vessels and nerve and to a slight extent from the obturator layer of the pelvic fascia, which covers it. The fibres converge rapidly, and are directed backward and downward, and terminate in four or five tendinous bands, which are found on its deep surface; these bands are reflected at a right angle over the inner surface of the tuberosity of the ischium, which is grooved for their reception; the groove is covered with cartilage, and lined by a synovial bursa. The muscle leaves the pelvis by the lesser sacro-sciatic foramen; and the tendinous bands unite into a single flattened tendon, which passes horizontally outward, and, after receiving the attachment of the Gemelli, is inserted into the fore part of the inner surface of the great trochanter in front of the Obturator externus. A synovial bursa, narrow and elongated in form, is usually found between the tendon of this muscle and the capsular ligament of the hip: it occasionally communicates with the bursa between the tendon and the tuberosity of the ischium, the two forming a single sac.

In order to display the peculiar appearances presented by the tendon of this muscle, it must be divided near its insertion and reflected inward.

Relations.—*Within the pelvis* this muscle is in relation, by its *anterior surface*, with the obturator membrane and inner surface of the anterior wall of the pelvis; by its *posterior surface*, with the pelvic and obturator fasciæ, which separate it from the Levator ani; and it is crossed by the internal pudic vessels and nerve. This surface forms the outer boundary of the ischio-rectal fossa. *External to the pelvis* it is covered by the Gluteus maximus, crossed by the great sciatic nerve, and rests on the back part of the hip-joint. As the tendon of the Obturator internus emerges from the lesser sacro-sciatic foramen it is overlapped by the two Gemelli, while nearer its insertion the Gemelli pass in front of it and form a groove in which the tendon lies.

The **Gemelli** are two small muscular fasciculi, accessories to the tendon of the Obturator internus, which is received into a groove between them. They are called *superior* and *inferior*.

The **Gemellus superior**, the smaller of the two, arises from the outer surface of the spine of the ischium, and, passing horizontally outward, becomes blended with the upper part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter. This muscle is sometimes wanting.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the capsule of the hip-joint; by its *upper border*, with the lower margin of the Piriformis; by its *lower border*, with the tendon of the Obturator internus.

The **Gemellus inferior** arises from the upper part of the tuberosity of the ischium, where it forms the lower edge of the groove for the Obturator internus tendon, and, passing horizontally outward, is blended with the lower part of the tendon of the Obturator internus, and is inserted with it into the inner surface of the great trochanter.

Relations.—By its *superficial surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *deep surface*, with the capsular ligament of the hip-joint; by its *upper border*, with the tendon of the Obturator internus; by its *lower border*, with the tendon of the Obturator externus and Quadratus femoris.

The **Quadratus femoris** is a short, flat muscle, quadrilateral in shape (hence its name), situated between the Gemellus inferior and the upper margin of the Adductor magnus. It arises from the upper part of the external lip of the tuberosity of the ischium, and, proceeding horizontally outward, is inserted into the upper part of the linea quadrata; that is, the line which crosses the posterior intertrochanteric line. A synovial bursa is often found between the under surface of this muscle and the lesser trochanter, which it covers.

Relations.—By its *posterior surface*, with the Gluteus maximus and the sciatic vessels and nerves; by its *anterior surface*, with the tendon of the Obturator externus and trochanter minor and with the capsule of the hip-joint; by its *upper border*, with the Gemellus inferior. Its *lower border* is separated from the Adductor magnus by the terminal branches of the internal circumflex vessels.

Dissection.—In order to expose the next muscle (the Obturator externus), it is necessary to remove the Psoas, Iliacus, Pectineus, and Adductor brevis and longus muscles from the front and inner side of the thigh, and the Gluteus maximus and Quadratus femoris from the back part. Its dissection should, consequently, be postponed until the muscles of the anterior and internal femoral regions have been explained.

The **Obturator externus** (Fig. 257) is a flat, triangular muscle, which covers the outer surface of the anterior wall of the pelvis. It arises from the margin of bone immediately around the inner side of the obturator foramen, viz., from the body and ramus of the os pubis and the ramus of the ischium; it also arises from the inner two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the canal for the passage of the obturator vessels and nerves. The fibres from the pubic arch extend on to the inner surface of the bone, from which they obtain a narrow origin between the margin of the foramen and the attachment of the membrane. The fibres converging pass backward, outward, and upward, and terminate in a tendon which runs across the back part of the hip-joint, and is inserted into the digital fossa of the femur.

Relations.—By its *anterior surface*, with the Psoas, Iliacus, Pectineus, Adductor magnus, and Adductor brevis; and more externally, with the neck of the femur and capsule of the hip-joint. The obturator artery and vein lie between this muscle and the obturator membrane; the superficial part of the obturator nerve lies above the muscle, and the deep branch perforates it; by its *posterior surface*, with the obturator membrane and Quadratus femoris.

Nerves.—The Gluteus maximus is supplied by the fifth lumbar and first and

second sacral nerves through the inferior gluteal nerve from the sacral plexus; the Gluteus medius and minimus, by the fourth and fifth lumbar and first sacral nerves through the superior gluteal; the Piriformis is supplied by the first and second sacral nerves; the Gemellus inferior and Quadratus femoris by the last lumbar and first sacral nerve; the Gemellus superior and Obturator internus by the fifth lumbar and first and second sacral nerves, and the Obturator externus by the second, third, and fourth lumbar nerves through the obturator.

FIG. 257.—Obturator externus muscle. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Actions.—The Gluteus maximus, when it takes its fixed point from the pelvis, extends the femur and brings the bent thigh into a line with the body. Taking its fixed point from below, it acts upon the pelvis, supporting it and the whole trunk upon the head of the femur, which is especially obvious in standing on one leg. Its most powerful action is to cause the body to regain the erect position after stooping by drawing the pelvis backward, being assisted in this action by the Biceps, Semitendinosus, and Semimembranosus. The Gluteus maximus is a tensor of the fascia lata, and by its connection with the ilio-tibial band it steadies the femur on the articular surface of the tibia during standing, when the extensor muscles are relaxed. The lower part of the muscle also acts as an adductor and external rotator of the limb. The Gluteus medius and minimus abduct the thigh when the limb is extended, and are principally called into action in supporting the body on one limb, in conjunction with the Tensor fasciæ femoris. Their anterior fibres, by drawing the great trochanter forward, rotate the thigh inward, in which action they are also assisted by the Tensor fasciæ femoris. The remaining muscles are powerful rotators of the thigh outward. In the sitting posture, when the thigh is flexed upon the pelvis, their action as rotator ceases, and they become abductors, with the exception of the Obturator externus, which still rotates the femur outward. When the femur is fixed, the Piriformis and Obturator muscles serve to draw the pelvis forward if it has been inclined backward, and assist in steadying it upon the head of the femur.

neath the internal lateral ligament. The tendon of the muscle at its origin expands into an aponeurosis which covers the upper part of its anterior surface: from this aponeurosis muscular fibres arise, and converge to another aponeurosis, which covers the lower part of its posterior surface and contracts into the tendon of insertion. The tendon of the muscle at its insertion gives off certain fibrous expansions; one of these, of considerable size, passes upward and outward to be inserted into the back part of the outer condyle of the femur, forming part of the posterior ligament of the knee-joint; a second is continued downward to the fascia which covers the Popliteus muscle. The tendon also sends a few fibres to join the internal lateral ligament of the joint.

The tendons of the two preceding muscles, with that of the Gracilis, form the inner hamstring.

Relations.—By its *superficial surface*, with the Gluteus maximus, Semitendinosus, Biceps, and fascia lata; by its *deep surface*, with the origin of the Quadratus femoris, popliteal vessels, Adductor magnus, and inner head of the Gastrocnemius, from which it is separated by a synovial bursa; by its *inner border*, with the Gracilis; by its *outer border*, with the great sciatic nerve, and its internal popliteal branch.

Nerves.—The muscles of this region are supplied by the first, second, and third sacral nerves through the great sciatic nerve.

Actions.—The hamstring muscles flex the leg upon the thigh. When the knee is semiflexed, the Biceps, in consequence of its oblique direction downward and outward, rotates the leg slightly outward; and the Semitendinosus, and to a slight extent the Semimembranosus, rotate the leg inward, assisting the Popliteus. Taking their fixed point from below, these muscles serve to support the pelvis upon the head of the femur and to draw the trunk directly backward, as in raising it from the stooping position or in feats of strength, when the body is thrown backward in the form of an arch. When the leg is extended on the thigh, they limit the amount of flexion of the trunk on the lower limbs.

Surgical Anatomy.—The tendons of these muscles occasionally require subcutaneous division in some forms of spurious ankylosis of the knee-joint dependent upon permanent contraction and rigidity of the Flexor muscles, or from stiffening of the ligamentous and other tissues surrounding the joint, the result of disease. This is effected by putting the tendon upon the stretch, and inserting a narrow, sharp-pointed knife between it and the skin: the cutting edge being then turned toward the tendon, it should be divided, taking great care that the wound in the skin is not at the same time enlarged. The relation of the external popliteal nerve to the tendon of the Biceps must always be borne in mind in dividing this tendon.

FIG. 258.—Muscles of the front of the leg.

III. MUSCLES AND FASCIÆ OF THE LEG.

These may be divided into three groups: those on the anterior, those on the posterior, and those on the outer side of the leg.

5. Anterior Tibio-fibular Region.

Tibialis anticus.

Extensor proprius hallucis.¹

Extensor longus digitorum.

Peroneus tertius.

Dissection (Fig. 252).—The knee should be bent, a block placed beneath it, and the foot kept in an extended position; then make an incision through the integument in the middle line of the leg to the ankle, and continue it along the dorsum of the foot to the toes. Make a second incision transversely across the ankle, and a third in the same direction across the bases of the toes; remove the flaps of integument included between these incisions in order to examine the deep fascia of the leg.

The **Deep Fascia of the Leg** forms a complete investment to the muscles, but is not continued over the subcutaneous surfaces of the bones. It is continuous above with the fascia lata, receiving an expansion from the tendon of the Biceps on the outer side, and from the tendons of the Sartorius, Gracilis, and Semitendinosus on the inner side; in front it blends with the periosteum covering the subcutaneous surface of the tibia, and with that covering the head and external malleolus of the fibula; below it is continuous with the annular ligaments of the ankle. It is thick and dense in the upper and anterior part of the leg, and gives attachment, by its deep surface, to the Tibialis anticus and Extensor longus digitorum muscles, but thinner behind, where it covers the Gastrocnemius and Soleus muscles. Over the popliteal space it is much strengthened by transverse fibres which stretch across from the inner to the outer hamstring muscles, and it is here perforated by the external saphenous vein. Its deep surface gives off, on the outer side of the leg, two strong intermuscular septa which enclose the Peronei muscles, and separate them from the muscles on the anterior and posterior tibial regions and several smaller and more slender processes which enclose the individual muscles in each region; at the same time a broad transverse intermuscular septum, called the *deep transverse fascia of the leg*, intervenes between the superficial and deep muscles in the posterior tibio-fibular region.

Remove the fascia by dividing it in the same direction as the integument, excepting opposite the ankle, where it should be left entire. Commence the removal of the fascia from below, opposite the tendons, and detach it in the line of direction of the muscular fibres.

The **Tibialis anticus** is situated on the outer side of the tibia; it is thick and fleshy at its upper part, tendinous below. It arises from the outer tuberosity and upper two-thirds of the external surface of the shaft of the tibia; from the adjoining part of the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septum between it and the Extensor longus digitorum: the fibres pass vertically downward, and terminate in a tendon which is apparent on the anterior surface of the muscle at the lower third of the leg. After passing through the innermost compartment of the anterior annular ligament, it is inserted into the inner and under surface of the internal cuneiform bone and base of the metatarsal bone of the great toe.

Relations.—By its *anterior surface*, with the fascia and with the annular ligament; by its *posterior surface*, with the interosseous membrane, tibia, ankle-joint, and inner side of the tarsus: this surface also overlaps the anterior tibial vessels

¹ There is no such word as "Hallux, -cis." It is the result of some ignorant blunder, copied until it has become established by usage; it has been thought better, therefore, to retain it. According to Lewis and Short the word is ALLEX, masculine; genitive, ALLICIS, the great toe, and the correct rendering would be Extensor proprius allieis. It is a rare word, and is sometimes spelt, but not so correctly, "Hallex." It is used by Plautus, in the *Pœnulus* V., v. 31, of a little man, as we might say "a hop-o'-my-thumb." "Tunc hic amator audes esse, allex viri" (To think of you daring to make up to her, you hop-o'-my-thumb!). The word "alex," sometimes spelt "allex," a fish sauce, is probably a different word altogether. It is used by Horace and Pliny.

and nerve in the upper part of the leg. By its *inner surface*, with the tibia; by its *outer surface*, with the Extensor longus digitorum and Extensor proprius hallucis, and the anterior tibial vessels and nerve.

The **Extensor proprius hallucis** is a thin, elongated, and flattened muscle situated between the Tibialis anticus and Extensor longus digitorum. It arises from the anterior surface of the fibula for about the middle two-fourths of its extent, its origin being internal to that of the Extensor longus digitorum; it also arises from the interosseous membrane to a similar extent. The fibres pass downward, and terminate in a tendon which occupies the anterior border of the muscle, passes through a distinct compartment in the lower portion of the annular ligament, crosses the anterior tibial vessels near the bend of the ankle, and is inserted into the base of the last phalanx of the great toe. Opposite the metatarso-phalangeal articulation the tendon gives off a thin prolongation on each side, which covers the surface of the joint. It usually sends an expansion from the inner side of the tendon, to be inserted into the base of the first phalanx.

Relations.—By its *anterior surface*, with the fascia and the anterior annular ligament; by its *posterior surface*, with the interosseous membrane, fibula, tibia, and ankle-joint; by its *outer side*, with the Extensor longus digitorum above, the dorsalis pedis vessels, anterior tibial nerve, and Extensor brevis digitorum below; by its *inner side*, with the Tibialis anticus and the anterior tibial vessels above. The muscle is external to the anterior tibial vessels in the upper part of the leg; but in the lower third its tendon crosses over them, so that it lies internal to them on the dorsum of the foot.

The **Extensor longus digitorum** is an elongated, flattened, penniform muscle situated the most externally of all the muscles on the fore part of the leg. It arises from the outer tuberosity of the tibia; from the upper three-fourths of the anterior surface of the shaft of the fibula; from the interosseous membrane; from the deep surface of the fascia; and from the intermuscular septa between it and the Tibialis anticus on the inner and the Peronei on the outer side. The tendon enters a canal in the annular ligament with the Peroneus tertius, and divides into four slips, which run across the dorsum of the foot and are inserted into the second and third phalanges of the four lesser toes. The mode in which the tendons are inserted is the following: The three inner tendons opposite the metatarso-phalangeal articulation are joined, on their outer side, by a tendon of the Extensor brevis digitorum. They all receive a fibrous expansion from the Interossei and Lumbricales, and then spread out into a broad aponeurosis, which covers the dorsal surface of the first phalanx: this aponeurosis, at the articulation of the first with the second phalanx, divides into three slips—a middle one, which is inserted into the base of the second phalanx, and two lateral slips, which, after uniting on the dorsal surface of the second phalanx, are continued onward, to be inserted into the base of the third.

Relations.—By its *anterior surface*, with the fascia and the annular ligament; by its *posterior surface*, with the fibula, interosseous membrane, ankle-joint, and Extensor brevis digitorum; by its *inner side*, with the Tibialis anticus, Extensor proprius hallucis, and anterior tibial vessels and nerve; by its *outer side*, with the Peroneus longus and brevis.

The **Peroneus tertius** is a part of the Extensor longus digitorum, and might be described as its fifth tendon. The fibres belonging to this tendon arise from the lower fourth of the anterior surface of the fibula, from the lower part of the interosseous membrane, and from an intermuscular septum between it and the Peroneus brevis. The tendon, after passing through the same canal in the annular ligament as the Extensor longus digitorum, is inserted into the dorsal surface of the base of the metatarsal bone of the little toe. This muscle is sometimes wanting.

Nerves.—These muscles are supplied by the fourth and fifth lumbar and first sacral nerves through the anterior tibial nerve.

Actions.—The Tibialis anticus and Peroneus tertius are the direct flexors of the

foot at the ankle-joint; the former muscle, when acting in conjunction with the Tibialis posticus, raises the inner border of the foot (*i. e.*, inverts the foot); and the latter, acting with the Peroneus brevis and longus, draws the outer border of the foot upward and the sole outward (*i. e.*, everts the foot). The Extensor longus digitorum and Extensor proprius hallucis extend the phalanges of the toes, and, continuing their action, flex the foot upon the leg. Taking their fixed point from below, in the erect posture, all these muscles serve to fix the bones of the leg in the perpendicular position, and give increased strength to the ankle-joint.

6. Posterior Tibio-fibular Region.

Dissection (Fig. 255).—Make a vertical incision along the middle line of the back of the leg, from the lower part of the popliteal space to the heel, connecting it below by a transverse incision extending between the two malleoli; the flaps of integument being removed, the fascia and muscles should be examined.

The muscles in this region of the leg are subdivided into two layers—superficial and deep. The superficial layer constitutes a powerful muscular mass, forming the calf of the leg. Their large size is one of the most characteristic features of the muscular apparatus in man, and bears a direct connection with his ordinary attitude and mode of progression.

Superficial Layer.

Gastrocnemius.

Soleus.

Plantaris.

The **Gastrocnemius** is the most superficial muscle, and forms the greater part of the calf. It arises by two heads, which are connected to the condyles of the femur by two strong flat tendons. The inner and larger head arises from a depression at the upper and back part of the inner condyle and from the adjacent part of the femur. The outer head arises from an impression on the outer side of the external condyle and from the posterior surface of the femur immediately above the condyle. Both heads, also, arise by a few tendinous and fleshy fibres from the ridges which are continued upward from the condyles to the linea aspera. Each tendon spreads out into an aponeurosis, which covers the posterior surface of that portion of the muscle to which it belongs; the muscular fibres of the inner head being thicker and extending lower than those of the outer. From the anterior surface of these tendinous expansions muscular fibres are given off. The fibres in the median line, which correspond to the accessory portions of the muscle derived from the bifurcations of the linea aspera, unite at an angle upon a median tendinous raphe below: the remaining fibres converge to an aponeurosis which covers the anterior surface of the muscle, and this, gradually contracting, unites with the tendon of the Soleus, and forms with it the tendo Achillis.

Relations.—By its *superficial surface*, with the fascia of the leg, which separates it from the external saphenous vein and nerve; by its *deep surface*, with the posterior ligament of the knee-joint, the Popliteus, Soleus, Plantaris, popliteal vessels, and internal popliteal nerve. The tendon of the inner head corresponds with the back part of the inner condyle, from which it is separated by a synovial bursa, which, in some cases, communicates with the cavity of the knee-joint. The tendon of the outer head contains a sesamoid fibro-cartilage (rarely osseous) where it plays over the corresponding outer condyle; and one is occasionally found in the tendon of the inner head.

The Gastrocnemius should be divided across, just below its origin, and turned downward, in order to expose the next two muscles.

The **Soleus** is a broad flat muscle situated immediately beneath the Gastrocnemius. It has received its name from its resemblance in shape to a sole-fish. It arises by tendinous fibres from the back part of the head of the fibula and from the upper third of the posterior surface of its shaft; from the oblique line of the

tibia and from the middle third of its internal border; some fibres also arise from a tendinous arch placed between the tibial and fibular origins of the muscle, beneath which the popliteal vessels and internal popliteal nerve pass. The fibres pass backward to an aponeurosis which covers the posterior surface of the muscle, and this, gradually becoming thicker and narrower, joins with the tendon of the Gastrocnemius, and forms with it the tendo Achillis.

Relations.—By its *superficial surface*, with the Gastrocnemius and Plantaris; by its *deep surface*, with the Flexor longus digitorum, Flexor longus hallucis, Tibialis posticus, and posterior tibial vessels and nerve, from which it is separated by the transverse intermuscular septum or deep transverse fascia of the leg.

The **Tendo Achillis**, the common tendon of the Gastrocnemius and Soleus,¹ is the thickest and strongest tendon in the body. It is about six inches in length, and commences about the middle of the leg, but receives fleshy fibres on its anterior surface nearly to its lower end. Gradually becoming contracted below, it is inserted into the lower part of the posterior surface of the os calcis, a synovial bursa being interposed between the tendon and the upper part of this surface. The tendon spreads out somewhat at its lower end, so that its narrowest part is usually about an inch and a half above its insertion. The tendon is covered by the fascia and the integument, and is separated from the deep muscles and vessels by a considerable interval filled up with areolar and adipose tissue. Along its outer side, but superficial to it, is the external saphenous vein.

The **Plantaris** is an extremely diminutive muscle placed between the Gastrocnemius and Soleus, and remarkable for its long and delicate tendon. It arises from the lower part of the outer prolongation of the linea aspera and from the posterior ligament of the knee-joint. It forms a small fusiform belly, about three or four inches in length, terminating in a long slender tendon which crosses obliquely between the two muscles of the calf, and, running along the inner border of the tendo Achillis, is inserted with it into the posterior part of the os calcis. This muscle is occasionally double, and is sometimes wanting. Occasionally, its tendon is lost in the internal annular ligament or in the fascia of the leg.

Nerves.—The Gastrocnemius is supplied by the first and second sacral nerves,

FIG. 259.—Muscles of the back of the leg. Superficial layer.

¹ These two muscles with a common tendon are by some anatomists classed together as one muscle, the *Triceps surae*, the two heads of origin of the Gastrocnemius and the Soleus constituting the three heads of the Triceps, and the tendo Achillis the single tendon of insertion.

and the *Plantaris* by the fourth and fifth lumbar and first sacral nerves through the internal popliteal. The *Soleus* is supplied by the fifth lumbar and first and second sacral nerves through the internal popliteal and posterior tibial.

Actions.—The muscles of the calf are the chief extensors of the foot at the ankle-joint. They possess considerable power, and are constantly called into use in standing, walking, dancing, and leaping; hence the large size they usually present. In walking these muscles draw powerfully upon the *os calcis*, raising the heel, and with it the entire body, from the ground; the body being thus supported on the raised foot, the opposite limb can be carried forward. In standing, the *Soleus*, taking its fixed point from below, steadies the leg upon the foot, and prevents the body from falling forward, to which there is a constant tendency from the superincumbent weight. The *Gastrocnemius*, acting from below, serves to flex the femur upon the tibia, assisted by the *Popliteus*. The *Plantaris* is the rudiment of a large muscle which exists in some of the lower animals and is continued over the *os calcis* to be inserted into the plantar fascia. In man it is an accessory to the *Gastrocnemius*, extending the ankle if the foot is free, or bending the knee if the foot is fixed. Possibly, acting from below, by its attachment to the posterior ligament of the knee-joint, it may pull that ligament backward during flexion, and so protect it from being compressed between the two articular surfaces.

Deep Layer (Fig. 260).

Popliteus.

Flexor longus digitorum.

Flexor longus hallucis.

Tibialis posticus.

Dissection.—Detach the *Soleus* from its attachment to the fibula and tibia, and turn it downward, when the deep layer of muscles is exposed, covered by the deep transverse fascia of the leg.

The **Deep Transverse Fascia** of the leg is a transversely placed, intermuscular septum, between the superficial and deep muscles in the posterior tibio-fibular region. On either side it is connected to the margins of the tibia and fibula. Above, where it covers the *Popliteus*, it is thick and dense, and receives an expansion from the tendon of the *Semimembranosus*; it is thinner in the middle of the leg, but below, where it covers the tendons passing behind the malleoli, it is thickened and continuous with the internal annular ligament.

This fascia should now be removed, commencing from below opposite the tendons, and detaching it from the muscles in the direction of their fibres.

The ***Popliteus*** is a thin, flat, triangular muscle, which forms part of the floor of the popliteal space. It arises by a strong tendon, about an inch in length, from a deep depression on the outer side of the external condyle of the femur, and from the posterior ligament of the knee-joint, and is inserted into the inner two-thirds of the triangular surface above the oblique line on the posterior surface of the shaft of the tibia, and into the tendinous expansion covering the surface of the muscle. The tendon of the muscle is covered by that of the *Biceps* and by the external lateral ligament of the knee-joint; it grooves the posterior border of the external semilunar fibro-cartilage, and is invested by the synovial membrane of the knee-joint.

Relations.—By its *superficial surface*, with the fascia covering it, which separates it from the *Gastrocnemius*, *Plantaris*, popliteal vessels, and internal popliteal nerve; by its *deep surface*, with the knee-joint and back of the tibia.

The ***Flexor longus hallucis*** is situated on the fibular side of the leg, and is the most superficial and largest of the three next muscles. It arises from the lower two-thirds of the posterior surface of the shaft of the fibula, with the exception of an inch at its lowest part; from the lower part of the interosseous membrane; from an intermuscular septum between it and the *Peronei*, externally; and from the fascia covering the *Tibialis posticus* internally. The fibres pass obliquely downward and backward, and terminate in a tendon which occupies nearly the whole length of the posterior surface of the muscle. This tendon occupies a groove on the posterior surface of the lower end of the tibia; it then lies in a second groove

on the posterior surface of the astragalus, and finally in a third groove, beneath the sustentaculum tali of the os calcis, and passes into the sole of the foot, where it runs forward between the two heads of the Flexor brevis hallucis, and is inserted into the base of the last phalanx of the great toe. The grooves in the astragalus and os calcis, which contain the tendon of the muscle, are converted by tendinous fibres into distinct canals lined by synovial membrane; and as the tendon crosses the sole of the foot, it is connected to the common flexor by a tendinous slip.

Relations.—By its *superficial surface*, with the Soleus and tendo Achillis, from which it is separated by the deep transverse fascia; by its *deep surface*, with the fibula, Tibialis posticus, the peroneal vessels, the lower part of the interosseous membrane, and the ankle-joint; by its *outer border*, with the Peronei; by its *inner border*, with the Tibialis posticus and posterior tibial vessels and nerve. In the sole of the foot it lies above the Abductor hallucis and Flexor longus digitorum.

The **Flexor longus digitorum** (*perforans*) is situated on the tibial side of the leg. At its origin it is thin and pointed, but gradually increases in size as it descends. It arises from the posterior surface of the shaft of the tibia, immediately below the oblique line to within three inches of its extremity, internal to the tibial origin of the Tibialis posticus; some fibres also arise from the fascia covering the Tibialis posticus. The fibres terminate in a tendon which runs nearly the whole length of the posterior surface of the muscle. This tendon passes behind the internal malleolus in a groove, common to it and the Tibialis posticus, but separated from the latter by a fibrous septum, each tendon being contained in a special sheath lined by a separate synovial membrane. It then passes obliquely forward and outward, superficial to the internal lateral ligament into the sole of the foot (Fig. 262), where, crossing superficially to the tendon of the Flexor longus hallucis,¹ to which it is connected by a strong tendinous slip, it becomes expanded, is joined by the Flexor accessorius, and finally divides into four tendons which are inserted into the bases of the last phalanges of the four lesser toes, each tendon passing through a fissure in the tendon of the Flexor brevis digitorum opposite the base of the first phalanges.

Relations.—*In the leg:* by its *superficial surface*, with the posterior tibial vessels and nerve, and the deep transverse fascia, which separates it from the Soleus muscle; by its *deep surface*, with the Tibia and Tibialis posticus. *In the foot* it is covered by the Abductor hallucis and Flexor brevis digitorum, and crosses superficial to the Flexor longus hallucis.

The **Tibialis posticus** lies between the two preceding muscles, and is the most deeply seated of all the muscles in the leg. It commences above by two pointed processes, separated by an angular interval, through which the anterior tibial vessels pass forward to the front of the leg. It arises from the whole of the posterior surface of the interosseous membrane, excepting its lowest part, from the outer portion of the posterior surface of the shaft of the tibia, between the

FIG. 260.—Muscles of the back of the leg. Deep layer.

¹ That is, in the order of dissection of the sole of the foot.

commencement of the oblique line above, and the junction of the middle and lower third of the shaft below; and from the upper two-thirds of the internal surface of the fibula; some fibres also arise from the deep transverse fascia and from the intermuscular septa, separating it from the adjacent muscles on each side. This muscle, in the lower fourth of the leg, passes in front of the Flexor longus digitorum, and terminates in a tendon which passes through a groove behind the inner malleolus with the tendon of that muscle, but enclosed in a separate sheath; it then passes through another sheath, over the internal lateral ligament into the foot, and then beneath the inferior calcaneo-navicular ligament, and is inserted into the tuberosity of the navicular and internal cuneiform bones. The tendon of this muscle contains a sesamoid fibro-cartilage as it passes over the navicular bone, and gives off fibrous expansions, one of which passes backward to the sustentaculum tali of the os calcis, others outward to the middle and external cuneiform and cuboid, and some forward to the bases of the second, third, and fourth metatarsal bones (Fig. 263).

Relations.—By its *superficial surface*, with the Soleus, from which it is separated by the deep transverse fascia, the Flexor longus digitorum, the posterior tibial vessels and nerve, and the peroneal vessels; by its *deep surface*, with the interosseous ligament, the tibia, fibula, and ankle-joint.

Nerves.—The Popliteus is supplied by the fourth and fifth lumbar and first sacral nerves, through the internal popliteal; the Flexor longus digitorum and Tibialis posticus by the fifth lumbar and first sacral; and the Flexor longus hallucis by the fifth lumbar and first and second sacral nerves through the posterior tibial.

Actions.—The Popliteus assists in flexing the leg upon the thigh; when the leg is flexed, it will rotate the tibia inward. It is especially called into action at the commencement of the act of bending the knee, inasmuch as it produces a slight inward rotation of the tibia, which is essential in the early stage of this movement. The Tibialis posticus is a direct extensor of the foot at the ankle-joint; acting in conjunction with the Tibialis anticus, it turns the sole of the foot inward (*i. e.*, inverts the foot), antagonizing the Peronei, which turn it outward (evert it). In the sole of the foot the tendon of the Tibialis posticus lies directly below the inferior calcaneo-scaphoid ligament, and is therefore an important factor in maintaining the arch of the foot. The Flexor longus digitorum and Flexor longus hallucis are the direct flexors of the phalanges, and, continuing their action, extend the foot upon the leg; they assist the Gastrocnemius and Soleus in extending the foot, as in the act of walking or in standing on tiptoe.

In consequence of the oblique direction of the tendon of the long flexor the toes would be drawn inward were it not for the Flexor accessorius muscle, which is inserted into the outer side of its tendon and draws it to the middle line of the foot during its action. Taking their fixed point from the foot, these muscles serve to maintain the upright posture by steadying the tibia and fibula perpendicularly upon the ankle-joint. They also serve to raise these bones from the oblique position they assume in the stooping posture.

7. Fibular Region.

Peroneus longus.

Peroneus brevis.

Dissection.—The muscles are readily exposed by removing the fascia covering their surface, from below upward, in the line of direction of their fibres.

The Peroneus longus is situated at the upper part of the outer side of the leg, and is the more superficial of the two muscles. It arises from the head and upper two-thirds of the outer surface of the shaft of the fibula, from the deep surface of the fascia, and from the intermuscular septa between it and the muscles on the front, and those on the back of the leg, occasionally also by a few fibres from the outer tuberosity of the tibia. Between its attachment to the head and to the shaft of the fibula there is a small interval of bone from which no muscular fibres arise; through this gap the external popliteal nerve passes beneath the muscle.

It terminates in a long tendon, which passes behind the outer malleolus, in a groove common to it and the tendon of the *Peroneus brevis*, behind which it lies, the groove being converted into a canal by a fibrous band, and the tendons invested by a common synovial membrane; it is then reflected obliquely forward across the outer side of the os calcis, below its peroneal tubercle, being contained in a separate fibrous sheath, lined by a prolongation of the synovial membrane which lines the groove behind the malleolus. Having reached the outer side of the cuboid bone, it runs in a groove on the under surface of that bone, which is converted into a canal by the long calcaneo-cuboid ligament, and is lined by a synovial membrane: the tendon then crosses the sole of the foot obliquely, and is inserted into the outer side of the base of the metatarsal bone of the great toe and the internal cuneiform bone. Occasionally it sends a slip to the base of the second metatarsal bone. The tendon changes its direction at two points: first, behind the external malleolus; secondly, on the outer side of the cuboid bone; in both of these situations the tendon is thickened, and in the latter a sesamoid fibro-cartilage, or sometimes a bone, is usually developed in its substance.

Relations.—By its *superficial surface*, with the fascia and integument; by its *deep surface*, with the fibula, external popliteal nerve, the *Peroneus brevis*, os calcis, and cuboid bone; by its *anterior border*, with an intermuscular septum, which intervenes between it and the *Extensor longus digitorum*; by its *posterior border*, with an intermuscular septum, which separates it from the *Soleus* above and the *Flexor longus hallucis* below.

The *Peroneus brevis* lies beneath the *Peroneus longus*, and is shorter and smaller than it. It arises from the lower two-thirds of the external surface of the shaft of the fibula, internal to the *Peroneus longus*, and from the intermuscular septa separating it from the adjacent muscles on the front and back part of the leg. The fibres pass vertically downward, and terminate in a tendon which runs in front of that of the preceding muscle through the same groove, behind the external malleolus, being contained in the same fibrous sheath and lubricated by the same synovial membrane. It then passes through a separate sheath on the outer side of the os calcis, above that for the tendon of the *Peroneus longus*, the two tendons being here separated by the peroneal tubercle, and is finally inserted into the tuberosity at the base of the metatarsal bone of the little toe, on its outer side.

Relations.—By its *superficial surface*, with the *Peroneus longus* and the fascia of the leg and foot; by its *deep surface*, with the fibula and outer side of the os calcis.

Nerves.—The *Peroneus longus* and *brevis* are supplied by the fourth and fifth lumbar and first sacral nerves through the musculo-cutaneous branch of the external popliteal nerve.

Actions.—The *Peroneus longus* and *brevis* extend the foot upon the leg, in conjunction with the *Tibialis posticus*, antagonizing the *Tibialis anticus* and *Peroneus tertius*, which are flexors of the foot. The *Peroneus longus* also everts the sole of the foot; hence the extreme eversion occasionally observed in fracture of the lower end of the fibula, where that bone offers no resistance to the action of this muscle. From the oblique direction of the *Peroneus longus* tendon across the sole of the foot it is an important agent in the maintenance of the transverse arch of the foot. Taking their fixed point below, the *Peronei* serve to steady the leg upon the foot. This is especially the case in standing upon one leg, when the tendency of the superincumbent weight is to throw the leg inward: the *Peroneus longus* overcomes this tendency by drawing on the outer side of the leg, and thus maintains the perpendicular direction of the limb.

Surgical Anatomy.—The student should now consider the position of the tendons of the various muscles of the leg, their relation with the ankle-joint and surrounding blood-vessels, and especially their action upon the foot, as their rigidity and contraction give rise to one or other of the kinds of deformity known as *club-foot*. The most simple and common deformity, and one

that is rarely, if ever, congenital, is the *talipes equinus*, the heel being raised by rigidity and contraction of the Gastrocnemius muscle, and the patient walking upon the ball of the foot. In the *talipes varus* the foot is forcibly adducted and the inner side of the sole raised, sometimes to a right angle with the ground, by the action of the *Tibialis anticus* and *posticus*. In the *talipes valgus* the outer edge of the foot is raised by the *Peronei* muscles, and the patient walks on the inner ankle. In the *talipes calcaneus* the toes are raised by the extensor muscles, the heel is depressed, and the patient walks upon it. Other varieties of deformity are met with, as the *talipes equino-varus*, *equino-valgus*, and *calcaneo-valgus*, whose names sufficiently indicate their nature. Of these, the *talipes equino-varus* is the most common congenital form: the heel is raised by the *tendo Achillis*, the inner border of the foot drawn upward by the *Tibialis anticus*, the anterior two-thirds twisted inward by the *Tibialis posticus*, and the arch increased by the contraction of the plantar fascia, so that the patient walks on the middle of the outer border of the foot. Each of these deformities may sometimes be successfully relieved by division of the opposing tendons and fascia: by this means the foot regains its proper position, and the tendons heal by the organization of lymph thrown out between the divided ends. The operation is easily performed by putting the contracted tendon upon the stretch, and dividing it by means of a narrow, sharp-pointed knife inserted beneath it.

Rupture of a few of the fibres of the *Gastrocnemius* or rupture of the *Plantaris* tendon not uncommonly occurs, especially in men somewhat advanced in life, from some sudden exertion, and frequently occurs during the game of lawn tennis, and is hence known as "lawn-tennis leg." The accident is accompanied by a sudden pain, and produces a sensation as if the individual had been struck a violent blow on the part. The *tendo Achillis* is also sometimes ruptured. It is stated that John Hunter ruptured his *tendo Achillis* whilst dancing at the age of forty.

IV. MUSCLES AND FASCIAE OF THE FOOT.

The fibrous bands, or thickened portions of the fascia of the leg, which bind down the tendons in front of and behind the ankle in their passage to the foot should now be examined; they are termed the *annular ligaments*, and are three in number—*anterior*, *internal*, and *external*.

The **Anterior Annular Ligament** consists of a superior or transverse portion, which binds down the Extensor tendons as they descend on the front of the tibia and fibula; and an inferior or Y-shaped portion, which retains them in connection with the tarsus, the two portions being connected by a thin intervening layer of fascia. The transverse portion is attached externally to the lower end of the fibula and internally to the tibia; above it is continuous with the fascia of the leg; it contains only one synovial sheath, for the tendon of the *Tibialis anticus*; the other tendons and the anterior tibial vessels and nerve passing beneath it, but without any distinct synovial sheath. The Y-shaped portion is placed in front of the ankle-joint, the stem of the Y being attached externally to the upper surface of the *os calcis*, in front of the depression for the *interosseous ligament*; it is directed inward, as a double layer, one lamina passing in front, and the other behind, the tendons of the *Peroneus tertius* and *Extensor longus digitorum*. At the inner border of the latter tendon these two layers join together, forming a sort of loop or sheath in which the tendons are enclosed, surrounded by a synovial membrane. From the inner extremity of this loop the two limbs of the Y diverge: one passes upward and inward, to be attached to the internal malleolus, passing over the *Extensor proprius hallucis* and the vessels and nerves, but enclosing the *Tibialis anticus* and its synovial sheath by a splitting of its fibres. The other limb extends downward and inward to be attached to the inner border of the plantar fascia, and passes over the tendons of the *Extensor proprius hallucis* and *Tibialis anticus* and also the vessels and nerves. These two tendons are contained in separate synovial sheaths situated beneath the ligament.

The **Internal Annular Ligament** is a strong fibrous band which extends from the inner malleolus above to the internal margin of the *os calcis* below, converting a series of grooves in this situation into canals for the passage of the tendons of the Flexor muscles and vessels into the sole of the foot. It is continuous by its upper border with the deep fascia of the leg, and by its lower border with the plantar fascia and the fibres of origin of the *Abductor hallucis* muscle. The four canals which it forms transmit, from within outward, first, the tendon of the *Tibialis posticus*; second, the tendon of the *Flexor longus digitorum*; third, the pos-

terior tibial vessels and nerve, which run through a broad space beneath the ligament; lastly, in a canal formed partly by the astragalus, the tendon of the Flexor longus hallucis. The canals for the tendons are lined by a separate synovial membrane.

The **External Annular Ligament** extends from the extremity of the outer malleolus to the outer surface of the os calcis: it binds down the tendons of the Peroneus longus and brevis muscles in their passage beneath the outer ankle. The two tendons are enclosed in one synovial sac.

Dissection of the Sole of the Foot.—The foot should be placed on a high block with the sole uppermost, and firmly secured in that position. Carry an incision round the heel and along the inner and outer borders of the foot to the great and little toes. This incision should divide the integument and thick layer of granular fat beneath until the fascia is visible; the skin and fat should then be removed from the fascia in a direction from behind forward, as seen in Fig. 255.

The **Plantar Fascia**, the densest of all the fibrous membranes, is of great strength, and consists of pearly-white glistening fibres, disposed, for the most part, longitudinally: it is divided into a central and two lateral portions.

The *central portion*, the thickest, is narrow behind and attached to the inner tubercle of the os calcis, posterior to the origin of the Flexor brevis digitorum, and, becoming broader and thinner in front, divides near the heads of the metatarsal bones into five processes, one for each of the toes. Each of these processes divides opposite the metatarso-phalangeal articulation into two strata, superficial and deep. The superficial stratum is inserted into the skin of the transverse sulcus which divides the toes from the sole. The deeper stratum divides into two slips which embrace the sides of the flexor tendons of the toes, and blend with the sheaths of the tendons, and laterally with the transverse metatarsal ligament, thus forming a series of arches through which the tendons of the short and long flexors pass to the toes. The intervals left between the five processes allow the digital vessels and nerves and the tendons of the Lumbricales muscles to become superficial. At the point of division of the fascia into processes and slips numerous transverse fibres are superadded, which serve to increase the strength of the fascia at this part by binding the processes together and connecting them with the integument. The central portion of the plantar fascia is continuous with the lateral portions at each side, and sends upward into the foot, at their point of junction, two strong vertical intermuscular septa, broader in front than behind, which separate the middle from the external and internal plantar group of muscles; from these, again, thinner transverse septa are derived, which separate the various layers of muscles in this region. The upper surface of this fascia gives attachment behind to the Flexor brevis digitorum muscle.

The *lateral portions* of the plantar fascia are thinner than the central piece, and cover the sides of the foot.

The *outer portion* covers the under surface of the Abductor minimi digiti; it is thick behind, thin in front, and extends from the os calcis, forward, to the base of the fifth metatarsal bone, into the outer side of which it is attached; it is continuous internally with the middle portion of the plantar fascia, and externally with the dorsal fascia.

The *inner portion* is very thin, and covers the Abductor hallucis muscle; it is attached behind to the internal annular ligament, and is continuous around the side of the foot with the dorsal fascia, and externally with the middle portion of the plantar fascia.

8. Dorsal Region.

Extensor brevis digitorum.

The **Fascia** on the dorsum of the foot is a thin membranous layer continuous above with the anterior margin of the annular ligament; it becomes gradually lost opposite the heads of the metatarsal bones, and on each side blends with the

lateral portions of the plantar fascia; it forms a sheath for the tendons placed on the dorsum of the foot. On the removal of this fascia the muscles and tendons of the dorsal region of the foot are exposed.

The **Extensor brevis digitorum** (Fig. 258) is a broad thin muscle which arises from the fore part of the upper and outer surfaces of the os calcis, in front of the groove for the Peroneus brevis, from the external calcaneo-astragaloid ligament, and from the common limb of the Y-shaped portion of the anterior annular ligament. It passes obliquely across the dorsum of the foot, and terminates in four tendons. The innermost, which is the largest, is inserted into the dorsal surface of the base of the first phalanx of the great toe, crossing the Dorsalis pedis artery; the other three, into the outer sides of the long extensor tendons of the second, third, and fourth toes.

Relations.—By its *superficial surface*, with the fascia of the foot, the tendons of the Extensor longus digitorum and Peroneus tertius; by its *deep surface*, with the tarsal and metatarsal arteries and bones and the Dorsal interossei muscles.

Nerves.—It is supplied by the anterior tibial nerve.

Actions.—The Extensor brevis digitorum is an accessory to the long Extensor, extending the phalanges of the four inner toes, but acting only on the first phalanx of the great toe. The obliquity of its direction counteracts the oblique movement given to the toes by the long Extensor, so that, both muscles acting together, the toes are evenly extended.

9. Plantar Region.

The muscles in the plantar region of the foot may be divided into three groups, in a similar manner to those in the hand. Those of the internal plantar region are connected with the great toe, and correspond with those of the thumb; those of the external plantar region are connected with the little toe, and correspond with those of the little finger; and those of the middle plantar region are connected with the tendons intervening between the two former groups. But in order to facilitate the dissection of these muscles it will be found more convenient to divide them into four layers, as they present themselves, in the order in which they are successively exposed.

First Layer.

Abductor hallucis.

Flexor brevis digitorum.

Abductor minimi digiti.

Dissection.—Remove the fascia on the inner and outer sides of the foot, commencing in front over the tendons and proceeding backward. The central portion should be divided transversely in the middle of the foot, and the two flaps dissected forward and backward.

The **Abductor hallucis** lies along the inner border of the foot. It arises from the inner tubercle on the under surface of the os calcis; from the internal annular ligament; from the plantar fascia; and from the intermuscular septum between it and the Flexor brevis digitorum. The fibres terminate in a tendon which is inserted, together with the innermost tendon of the Flexor brevis hallucis, into the inner side of the base of the first phalanx of the great toe.

Relations.—By its *superficial surface*, with the plantar fascia; by its *deep surface*, with the Flexor brevis hallucis, the Flexor accessorius, and the tendons of the Flexor longus digitorum and Flexor longus hallucis, the Tibialis anticus and posticus, the plantar vessels and nerves. Its outer border is in relation to the Flexor brevis digitorum.

The **Flexor brevis digitorum** (*perforatus*) lies in the middle of the sole of the foot, immediately beneath¹ the plantar fascia, with which it is firmly united. It arises by a narrow tendinous process, from the inner tubercle

¹ That is, in order of dissection of the sole of the foot.

of the os calcis, from the central part of the plantar fascia, and from the intermuscular septa between it and the adjacent muscles. It passes forward, and divides into four tendons, one for each of the four outer toes. Opposite the bases of the first phalanges each tendon divides into two slips, to allow of the passage of the corresponding tendon of the Flexor longus digitorum; the two portions of the tendon then unite and form a grooved channel for the reception of the accompanying long flexor tendon. Finally, they divide a second time, to be inserted into the sides of the second phalanges about their middle. The mode of division of the tendons of the Flexor brevis digitorum and their insertion into the phalanges is analogous to the Flexor sublimis digitorum in the hand.

Relations.—By its *superficial surface*, with the plantar fascia; by its *deep surface*, with the Flexor accessorius, the Lumbricales, the tendons of the Flexor longus digitorum, and the external plantar vessels and nerve, from which it is separated by a thin layer of fascia. The *outer* and *inner borders* are separated from the adjacent muscles by means of vertical prolongations of the plantar fascia.

Fibrous Sheaths of the Flexor Tendons.—These are not so well marked as in the fingers. The flexor tendons of the toes as they run along the phalanges are retained against the bones by a fibrous sheath, forming osseo-aponeurotic canals. These sheaths are formed by strong fibrous bands which arch across the tendons and are attached on each side to the margins of the phalanges. Opposite the middle of the proximal and second phalanges the sheath is very strong, and the fibres pass transversely, but opposite the joints it is much thinner, and the fibres pass obliquely. Each sheath is lined by a synovial membrane which is reflected on the contained tendon.

The **Abductor minimi digiti** lies along the outer border of the foot. It arises, by a very broad origin, from the outer tubercle of the os calcis, from the under surface of the os calcis between the two tubercles, from the fore part of the inner tubercle, from the plantar fascia and the intermuscular septum, between it and the Flexor brevis digitorum. Its tendon, after gliding over a smooth facet on the under surface of the base of the fifth metatarsal bone, is inserted with the short Flexor of the little toe into the outer side of the base of the first phalanx of this toe.

Relations.—By its *superficial surface*, with the plantar fascia; by its *deep surface*, with the Flexor accessorius, the Flexor brevis minimi digiti, the long plantar ligament, and the tendon of the Peroneus longus. On its *inner side* are the external plantar vessels and nerve, and it is separated from the Flexor brevis digitorum by a vertical septum of fascia.

Dissection.—The muscles of the superficial layer should be divided at their origin by inserting the knife beneath each, and cutting obliquely backward, so as to detach them from the bone; they should then be drawn forward, in order to expose the second layer, but not cut

FIG. 261.—Muscles of the sole of the foot. First Layer.

posticus, which is attached to that bone. The muscle divides, in front, into two portions, which are inserted into the inner and outer sides of the base of the first phalanx of the great toe, a sesamoid bone being developed in each tendon at its insertion. The inner portion of this muscle is blended with the Abductor hallucis previous to its insertion, the outer with the Adductor obliquus hallucis, and the tendon of the Flexor longus hallucis lies in a groove between them.

Relations.—By its *superficial surface*, with the Abductor hallucis and the tendon of the Flexor longus hallucis; by its *deep surface*, with the tendon of the Peroneus longus and metatarsal bone of the great toe; by its *inner border*, with the Abductor hallucis; by its *outer border*, with the Adductor obliquus hallucis.

The **Adductor obliquus hallucis** is a large, thick, fleshy mass passing obliquely across the foot and occupying the hollow space between the four inner metatarsal bones. It arises from the tarsal extremities of the second, third and fourth metatarsal bones, and from the sheath of the tendon of the Peroneus longus, and is inserted, together with the outer portion of the Flexor brevis hallucis, into the outer side of the base of the first phalanx of the great toe.

The small muscles of the great toe, the Abductor, Flexor brevis, Adductor obliquus, and Adductor transversus, like the similar muscles of the thumb, give off fibrous expansions, at their insertions, to blend with the long Extensor tendon.

The **Flexor brevis minimi digiti** lies on the metatarsal bone of the little toe, and much resembles one of the Interossei. It arises from the base of the metatarsal bone of the little toe, and from the sheath of the Peroneus longus; its tendon is inserted into the base of the first phalanx of the little toe on its outer side. Occasionally some of the deeper fibres of the muscle are inserted into the outer part of the distal half of the fifth metatarsal bone; these are described by some as a distinct muscle, the *Opponens minimi digiti*.

Relations.—By its *superficial surface*, with the plantar fascia and tendon of the Abductor minimi digiti; by its *deep surface*, with the fifth metatarsal bone.

The **Adductor transversus hallucis** (*Transversus pedis*) is a narrow, flat, muscular fasciculus, stretched transversely across the heads of the metatarsal bones, between them and the flexor tendons. It arises from the inferior metatarso-phalangeal ligaments of the three outer toes, sometimes only from the third and fourth and from the transverse ligament of the metatarsus; and is inserted into the outer side of the first phalanx of the great toe, its fibres being blended with the tendon of insertion of the Adductor obliquus hallucis.

Relations.—By its *superficial surface*, with the tendons of the long and short Flexors and Lumbricales; by its *deep surface*, with the Interossei.

FIG. 263.—Muscles of the sole of the foot. Third layer.

Fourth Layer.

The Interossei.

The **Interossei muscles** in the foot are similar to those in the hand, with this exception, that they are grouped around the middle line of the *second* toe, instead of the middle line of the *third* finger, as in the hand. They are seven in number, and consist of two groups, dorsal and plantar.

The **Dorsal interossei**, four in number, are situated between the metatarsal bones. They are bipenniform muscles, arising by two heads from the adjacent sides of the metatarsal bones, between which they are placed; their tendons are inserted into the bases of the first phalanges, and into the aponeurosis of the common extensor tendon. In the angular interval left between the heads of

FIG. 264.—The Dorsal interossei. Left foot.

FIG. 265.—The Plantar interossei. Left foot.

each muscle at its posterior extremity the perforating arteries pass to the dorsum of the foot, except in the First interosseous muscle, where the interval allows the passage of the communicating branch of the dorsalis pedis artery. The First dorsal interosseous muscle is inserted into the inner side of the second toe; the other three are inserted into the outer sides of the second, third, and fourth toes.

The **Plantar interossei**, three in number, lie beneath, rather than between, the metatarsal bones. They are single muscles, and are each connected with but one metatarsal bone. They arise from the base and inner sides of the shaft of the third, fourth, and fifth metatarsal bones, and are inserted into the inner sides of the bases of the first phalanges of the same toes, and into the aponeurosis of the common extensor tendon.

Nerves.—The Flexor brevis digitorum, the Flexor brevis and Abductor hallucis, and the innermost Lumbrical¹ are supplied by the internal plantar nerve. All

¹ Formerly the two inner Lumbricales were described as being supplied by the internal plantar nerve. Brooks, however (*Journal of Anatomy*, vol. xxi., p. 575), in ten dissections found that in nine of them only the inner Lumbrical obtained its nerve supply from this source. In the tenth instance the first and second Lumbricales were supplied by both external and internal plantar.

the other muscles in the sole of the foot by the external plantar. The first dorsal interosseous muscle frequently receives an extra filament from the internal branch of the anterior tibial nerve on the dorsum of the foot, and the second dorsal interosseous a twig from the external branch of the same nerve.

Actions.—All the muscles of the foot act upon the toes, and for purposes of description as regards their action may be grouped as Abductors, Adductors, Flexors, or Extensors. The *Abductors* are the Dorsal interossei, the Abductor hallucis, and the Abductor minimi digiti. The Dorsal interossei are abductors from an imaginary line passing through the axis of the second toe, so that the first muscle draws the second toe inward, toward the great toe; the second muscle draws the same toe, outward; the third draws the third toe, and the fourth draws the fourth toe, in the same direction. Like the interossei in the hand, they also flex the proximal phalanges and extend the two terminal phalanges. The Abductor hallucis abducts the great toe from the others, and also flexes the proximal phalanx of this toe. And in the same way the action of the Abductor minimi digiti is twofold—as an abductor of this toe from the others, and also as a flexor of the proximal phalanx. The *Adductors* are the Plantar interossei, the Adductor obliquus hallucis, and the Adductor transversus hallucis. The plantar interosseous muscles adduct the third, fourth, and fifth toes toward the imaginary line passing through the second toe, and by means of their insertion into the aponeurosis of the extensor tendon they flex the proximal phalanges and extend the two terminal phalanges. The Adductor obliquus hallucis is chiefly concerned in adducting the great toe toward the second one, but also assists in flexing this toe. The Adductor transversus hallucis approximates all the toes, and thus increases the curve of the transverse arch of the metatarsus. The *Flexors* are the Flexor brevis digitorum, the Flexor accessorius, the Flexor brevis hallucis, the Flexor brevis minimi digiti, and the Lumbricales. The Flexor brevis digitorum flexes the second phalanges upon the first, and, continuing its action, may flex the first phalanges also and bring the toes together. The Flexor accessorius assists the Long flexor of the toes, and converts the oblique pull of the tendons of that muscle into a direct backward pull upon the toes. The Flexor brevis minimi digiti flexes the little toe and draws its metatarsal bone downward and inward. The Lumbricales, like the corresponding muscles in the hand, assist in flexing the proximal phalanx, and by their insertion into the long Extensor tendon aid in straightening the two terminal phalanges. The only muscle in the *Extensor* group is the Extensor brevis digitorum. It extends the first phalanx of the great toe, and assists the long Extensor in extending the next three toes, and at the same time gives to the toes an outward direction when they are extended.

Surface Form.—Of the muscles of the thigh, those of the iliac region have no influence on surface form, while those of the anterior femoral region, being to a great extent superficial, largely contribute to the surface form of this part of the body. The *Tensor fasciæ femoris* produces a broad elevation immediately below the anterior portion of the crest of the ilium and behind the anterior superior spinous process. From its lower border a longitudinal groove, corresponding to the ilio-tibial band, may be seen running down the outer side of the thigh to the outer side of the knee-joint. The *Sartorius* muscle, when it is brought into action by flexing the leg on the thigh and the thigh on the pelvis, and rotating the thigh outward, presents a well-marked surface form. At its upper part, where it constitutes the outer boundary of Scarpa's triangle, it forms a prominent oblique ridge, which becomes changed into a flattened plane below, and this gradually merges in a general fulness on the inner side of the knee-joint. When the Sartorius is not in action, a depression exists between the Extensor quadriceps and the Adductor muscles, running obliquely downward and inward from the apex of Scarpa's triangle to the inner side of the knee, which corresponds to this muscle. In the depressed angle formed by the divergence of the Sartorius and Tensor fasciæ femoris muscles, just below the anterior superior spinous process of the ilium, the *Rectus femoris* muscle appears, and, below this, determines to a great extent the convex form of the front of the thigh. In a well-developed subject the borders of the muscle, when in action, are clearly to be defined. The *Vastus externus* forms a long flattened plane on the outer side of the thigh, traversed by the longitudinal groove formed by the ilio-tibial band. The *Vastus internus*, on the inner side of the lower half of the thigh, gives rise to a considerable prominence, which increases toward

the knee and terminates somewhat abruptly in this situation with a full, curved outline. The *Crureus* and *Subcrureus* are completely hidden, and do not directly influence surface form. The *Adductor muscles*, constituting the internal femoral group, are not to be individually distinguished from each other, with the exception of the upper tendon of the *Adductor longus* and the lower tendon of the *Adductor magnus*. The upper tendon of the *Adductor longus*, when the muscle is in action, stands out as a prominent ridge, which runs obliquely downward and outward from the neighborhood of the pubic spine, and forms the inner boundary of a flattened triangular space on the upper part of the front of the thigh, known as Scarpa's triangle. The lower tendon of the *Adductor magnus* can be distinctly felt as a short ridge extending down to the *Adductor tubercle* on the internal condyle, between the *Sartorius* and *Vastus internus*. The *Adductor* group of muscles fills in the triangular space at the upper part of the thigh, formed between the oblique femur and the pelvic wall, and to them is due the contour of the inner border of the thigh, the *Gracilis* largely contributing to the smoothness of the outline. These muscles are not marked off on the surface from those of the posterior femoral region by any intermuscular marking; but on the outer side of the thigh these latter muscles are defined from the *Vastus externus* by a distinct marking, corresponding to the external intermuscular septum. The *Gluteus maximus* and a part of the *Gluteus medius* are the only muscles of the buttock which influence surface form. The other part of the *Gluteus medius*, the *Gluteus minimus*, and the *External rotators* are completely hidden. The *Gluteus maximus* forms the full rounded outline of the buttock; it is more prominent behind, compressed in front, and terminates at its tendinous insertion in a depression immediately behind the great trochanter. Its lower border does not correspond to the gluteal fold, but is much more oblique, being marked by a line drawn from the side of the coccyx to the junction of the upper with the lower two-thirds of the thigh on the outer side. From beneath the lower margin of this muscle the *hamstring muscles* appear, at first narrow and not well marked, but as they descend becoming more prominent and widened out, and eventually dividing into two well-marked ridges, which constitute the upper boundaries of the popliteal space, and are formed by the tendons of the inner and outer hamstring muscles respectively. In the upper part of the thigh these muscles are not to be individually distinguished from each other, but lower down the separation between the *Semitendinosus* and *Semimembranosus* is denoted by a slight intermuscular marking. The external hamstring tendon formed by the *Biceps* is seen as a thick cord running down to the head of the fibula. The inner hamstring tendons comprise the *Semitendinosus*, the *Semimembranosus*, and the *Gracilis*. The *Semitendinosus* is the most internal of these, and can be felt, in certain positions of the limb, as a sharp cord; the *Semimembranosus* is thick, and the *Gracilis* is situated a little farther forward than the other two. All the muscles on the front of the leg appear to a certain extent somewhere on the surface, but the form of this region is mainly dependent upon the *Tibialis anticus* and the *Extensor longus digitorum*. The *Tibialis anticus* is well marked, and presents a fusiform enlargement at the outer side of the tibia, and projects beyond the crest of the shin-bone. From the muscular mass its tendon may be traced downward, standing out boldly, when the muscle is in action, on the front of the tibia and ankle-joint, and coursing down to its insertion along the inner border of the foot. A well-marked groove separates this muscle externally from the *Extensor longus digitorum*, which fills up the rest of the space between the upper part of the shaft of the tibia and fibula. It does not present so bold an outline as the *Tibialis anticus*, and its tendon below, diverging from the tendon of the *Tibialis anticus*, forms with the latter a sort of plane, in which may be seen the tendon of the *Extensor proprius hallucis*. A groove on the outer side of the *Extensor longus digitorum*, seen most plainly when the muscle is in action, separates the tendon from a slight eminence corresponding to the *Peroneus tertius*. The fleshy fibres of the *Peroneus longus* are strongly marked at the upper part of the outer side of the leg, especially when the muscle is in action. It forms a bold swelling, separated by furrows from the *Extensor longus digitorum* in front and the *Soleus* behind. Below, the fleshy fibres terminate abruptly in a tendon which overlaps the more flattened form of the *Peroneus brevis*. At the external malleolus the tendon of the *Peroneus brevis* is more marked than that of the *Peroneus longus*. On the dorsum of the foot the tendons of the *Extensor* muscles, emerging from beneath the anterior annular ligament, spread out and can be distinguished in the following order: The most internal and largest is the *Tibialis anticus*, then the *Extensor proprius hallucis*; next comes the *Extensor longus digitorum*, dividing into four tendons to the four outer toes; and lastly, most externally, is the *Peroneus tertius*. The flattened form of the dorsum of the foot is relieved by the rounded outline of the fleshy belly of the *Extensor brevis digitorum*, which forms a soft fullness on the outer side of the tarsus in front of the external malleolus, and by the *Dorsal interossei*, which bulge between the metatarsal bones. At the back of the knee is the popliteal space, bounded above by the tendons of the hamstring muscle; below, by the two heads of the *Gastrocnemius*. Below this space is the prominent fleshy mass of the calf of the leg, produced by the *Gastrocnemius* and *Soleus*. When these muscles are in action, as in standing on tiptoe, the borders of the *Gastrocnemius* are well defined, presenting two curved lines, which converge to the tendon of insertion. Of these borders, the inner is more prominent than the outer. The fleshy mass of the calf terminates somewhat abruptly below in the tendo Achillis, which stands out prominently on the lower part of the back of the leg. It presents a somewhat tapering form in the upper three-fourths of its extent, but widens out slightly below. When the muscles of the calf are in action, the lateral portions of the *Soleus* may be seen, forming

curved eminences, of which the outer is the longer, on either side of the Gastrocnemius. Behind the inner border of the lower part of the shaft of the tibia a well-marked ridge, produced by the tendon of the Tibialis posticus, is visible when this muscle is in a state of contraction.

On the sole of the foot the superficial layer of muscles influences surface form; the *Abductor minimi digiti* most markedly. This muscle forms a narrow rounded elevation along the outer border of the foot, while the *Abductor hallucis* does the same, though to a less extent, on the inner side. The *Flexor brevis digitorum*, bound down by the plantar fascia, is not very apparent; it produces a flattened form, covered by the thickened skin of the sole, which is here thrown into numerous wrinkles.

SURGICAL ANATOMY OF THE LOWER EXTREMITY.

The student should now consider the effects produced by the action of the various muscles in fractures of the bones of the lower extremity. The more common forms of fractures are selected for illustration and description.

In fracture of the *neck of the femur internal to the capsular ligament* (Fig. 266) the characteristic marks are slight shortening of the limb and eversion of the foot, neither of which symptoms occurs, however, in some cases until some time after

FIG. 266.—Fracture of the neck of the femur within the capsular ligament.

FIG. 267.—Fracture of the femur below the trochanters.

the injury. The eversion is caused by the weight of the limb rotating it outward. The shortening is produced by the action of the Glutei, and by the Rectus femoris in front and the Biceps, Semitendinosus, and Semimembranosus behind.

In fracture of the *femur just below the trochanters* (Fig. 267), the upper fragment, the portion chiefly displaced, is tilted forward almost at right angles with the pelvis by the combined action of the Psoas and Iliacus, and, at the same time, everted and drawn outward by the External rotator and Glutei muscles, causing a marked prominence at the upper and outer side of the thigh, and much pain from the bruising and laceration of the muscles. The limb is shortened, in consequence of the lower fragment being drawn upward by the Rectus in front, and the Biceps, Semimembranosus, and Semitendinosus behind, and is at the same time everted. This fracture may be reduced in two different methods: either by direct relaxation of all the opposing muscles, to effect which the limb should be put up in such a manner that the thigh is flexed on the pelvis and the leg on the thigh; or by overcoming the contraction of the muscles by continued extension, which may be effected by means of the long splint.

Oblique fracture of the femur *immediately above the condyles* (Fig. 268) is a formidable

injury, and attended with considerable displacement. On examination of the limb the lower fragment may be felt deep in the popliteal space, being drawn backward by the Gastrocnemius and Plantaris muscles, and upward by the Hamstring and Rectus muscles. The pointed end of the upper fragment is drawn inward by the Pectineus and Adductor muscles, and tilted forward by the Psoas and Iliacus, piercing the Rectus muscle and occasionally the integument. Relaxation of these muscles and direct approximation of the broken fragments are effected by placing the limb on a double inclined plane. The greatest care is requisite in keeping the pointed extremity of the upper fragment in proper position; otherwise, after union of the fracture, the power of extension of the limb is partially destroyed, from the Rectus muscle being held down by the fractured end of the

FIG. 268.—Fracture of the femur above the condyles.

FIG. 269.—Fracture of the patella.

FIG. 270.—Oblique fracture of the shaft of the tibia.

bone, and from the patella, when elevated, being drawn upward against the projecting fragment. In fracture of the *patella* (Fig. 269) the fragments are separated by the effusion which

FIG. 271.—Fracture of the fibula with dislocation of the foot outward—"Pott's fracture."

takes place into the joint, and possibly by the action of the Quadriceps extensor; the extent of separation of the two fragments depending upon the degree of laceration of the ligamentous structures around the bone.

In oblique fracture of the *shaft of the tibia* (Fig. 270), if the fracture has taken place obliquely from above, downward and forward, the fragments ride over one another, the lower fragments being drawn backward and upward by the powerful action of the muscles of the calf; the pointed extremity of the upper fragment projects forward immediately beneath the integument, often protruding through it and rendering the fracture a compound one. If the direction of the fracture is the reverse of that shown in the figure, the pointed extremity of the lower fragment projects forward, riding upon the lower end of the upper one. By bending the knee, which relaxes the opposing muscles, and making extension from the ankle and counter-extension at the knee, the fragments may be brought into apposition. It is often necessary, however, in compound fracture, to remove a portion of the projecting bone with the saw before complete adaptation can be effected.

Fracture of the *fibula with dislocation of the foot outward* (Fig. 271), commonly known as "Pott's fracture," is one of the most frequent injuries of the ankle-joint. The fibula is fractured about three inches above the ankle; in addition to this the internal malleolus is broken off, or the deltoid ligament torn through, and the end of the tibia displaced from the corresponding surface of the astragalus. The foot is markedly everted, and the sharp edge of the upper end of the fractured malleolus presses strongly against the skin; at the same time, the heel is drawn up by the muscles of the calf. This injury can generally be reduced by flexing the leg at right angles with the thigh, which relaxes all the opposing muscles, and by making extension from the ankle and counter-extension at the knee.

THE BLOOD-VASCULAR SYSTEM.

THE blood-vascular system comprises the heart and blood-vessels with their contained fluid, the blood. The composition of the blood and the minute anatomy of the blood-vessels will be considered in the section on Histology.

The Heart is the central organ of the entire system, and consists of a hollow muscle; by its contraction the blood is pumped to all parts of the body through a complicated series of tubes, termed *arteries*. The arteries undergo enormous ramification in their course throughout the body, and end in very minute vessels, called *arterioles*, which in their turn open into a close-meshed network of microscopic vessels, termed *capillaries*. After the blood has passed through the capillaries it is collected into a series of larger vessels, called *veins*, by which it is again returned to the heart. The passage of the blood through the heart and blood-vessels constitutes what is termed the *circulation* of the blood, of which the following is an outline.

The human heart is divided by a septum into two halves, right and left, each half being further constricted into two cavities, the upper of the two being termed the *auricle* and the lower the *ventricle*. The heart therefore consists of four chambers or cavities, two forming the right half, the right auricle and right ventricle, and two the left half, the left auricle and left ventricle. The right half of the heart contains venous or impure blood; the left, arterial or pure blood. From the cavity of the left ventricle the pure blood is carried into a large artery, the *aorta*, through the numerous branches of which it is distributed to all parts of the body, with the exception of the lungs. In its passage through the capillaries of the body the blood gives up to the tissues the materials necessary for their growth and nourishment, and at the same time receives from the tissues the waste products resulting from their metabolism, and in doing so becomes changed from arterial or pure blood into venous or impure blood, which is collected by the veins and through them returned to the right auricle of the heart. From this cavity the impure blood passes into the right ventricle, from which it is conveyed through the *pulmonary arteries* to the lungs. In the capillaries of the lungs it again becomes arterialized, and is then carried to the left auricle by the *pulmonary veins*. From this cavity it passes into that of the left ventricle, from which the cycle once more begins.

The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or *systemic* circulation, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or *pulmonary* circulation.

It is necessary, however, to state that the blood which circulates through the spleen, pancreas, stomach, small intestine, and the greater part of the large intestine is not returned directly from these organs to the heart, but is collected into a large vein, termed the *portal vein*, by which it is carried to the liver. In the liver this vein divides, after the manner of an artery, and ultimately ends in capillary vessels, from which the rootlets of a series of veins, called the *hepatic veins*, arise; these carry the blood into the inferior vena cava, which conveys it to the right auricle.

From this it will be seen that the blood contained in the portal vein passes through two sets of capillary vessels: (1) those in the spleen, pancreas, stomach, etc., and (2) those in the liver.

Speaking generally, the arteries may be said to contain pure, and the veins impure, blood. This is true of the systemic, but not of the pulmonary, vessels, since it has been seen that the impure blood is conveyed from the heart to the

lungs by the pulmonary arteries, and the pure blood returned from the lungs to the heart by the pulmonary veins. Arteries, therefore, must be defined as vessels which convey blood *from* the heart, and veins as vessels which return blood *to* the heart.

The heart and lungs are contained within the cavity of the thorax, the walls of which afford them protection. The heart lies between the two lungs, and is there enclosed within a membranous bag, the *pericardium*, while each lung is invested by a serous membrane, the *pleura*. The skeleton of the thorax and the shape and boundaries of the cavity will be described in the section on General Anatomy.

The Cavity of the Thorax.—The capacity of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera; and (2) the cavity extends above the first rib into the neck. The size of the cavity of the thorax is constantly varying during life with the movements of the ribs and Diaphragm, and with the degree of distention of the abdominal viscera. From the collapsed state of the lungs, as seen when the thorax is opened, in the dead body, it would appear as if the viscera only partly filled the cavity of the thorax, but during life there is no vacant space, that which is seen after death being filled up by the expanded lungs.

The Upper Opening of the Thorax.—The parts which pass through the upper opening of the thorax are, from before backward in or near the middle line, the Sternohyoid and Sterno-thyroid muscles, the remains of the thymus gland, the trachea, œsophagus, thoracic duct, the inferior thyroid veins, and the Longus colli muscle of each side; at the sides, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary and superior intercostal arteries, the right and left innominate veins, the pneumogastric, cardiac, phrenic, and sympathetic nerves, the anterior branch of the first dorsal nerve, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the margin of the first rib.

The Lower Opening of the Thorax is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm (see page 325) closes in the opening, forming the floor of the thorax. The floor is flatter at the centre than at the sides, and is higher on the right side than on the left, corresponding in the dead body to the upper border of the fifth costal cartilage on the former, and to the corresponding part of the sixth costal cartilage on the latter. From the highest point on each side the floor slopes suddenly downward to the attachment

FIG. 272.—Diagram to show the course of the circulation of the blood.

of the Diaphragm to the ribs; this is more marked behind than in front, so that only a narrow space is left between it and the wall of the thorax.

THE PERICARDIUM.

The **Pericardium** (Figs. 273, 274) is a conical membranous sac in which the heart and the commencement of the great vessels are contained. It is placed behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleuræ.

FIG. 273.—Pericardium, from in front. The sac has been distended with plaster. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Its *apex* is directed upward, and surrounds the great vessels about two inches above their origin from the base of the heart. Its *base* is attached to the central tendon and to the left part of the adjoining muscular structure of the Diaphragm. *In front* it is separated from the sternum by the remains of the thymus gland above and a little loose areolar tissue below, and is covered by the margins of the lungs, especially the left. *Behind*, it rests upon the bronchi, the œsophagus, and the descending aorta. *Laterally*, it is covered by the pleuræ, and is in relation to the inner surface of the lungs; the phrenic nerve with its accompanying vessels descends between the pericardium and pleura on either side.

Structure of the Pericardium.—The pericardium is a fibro-serous membrane, and consists, therefore, of two layers, an external fibrous and an internal serous.

The *fibrous layer* is a strong, dense membrane. Above, it surrounds the great vessels arising from the base of the heart, on which it is continued in the form of tubular prolongations which are gradually lost upon their external coat, the strongest being that which encloses the aorta. The pericardium may be traced over these vessels, to become continuous with the deep layer of the cervical fascia. In front the pericardium is connected to the posterior surface of the sternum by two fibrous bands, the *superior* and *inferior sterno-pericardiac ligaments*, the upper

FIG. 274.—Pericardium, from behind. (From the same preparation as the preceding figure.)

passing to the manubrium, and the lower to the ensiform cartilage. On each side of the ascending aorta it sends upward a diverticulum: the one on the left side, somewhat conical in shape, passes upward and outward, between the arch of the aorta and the pulmonary artery, as far as the ductus arteriosus, where it terminates in a cæcal extremity, which is attached by loose connective tissue to the obliterated duct (Fig. 273). The one on the right side passes upward and to the right, between the ascending aorta and vena cava superior, and also terminates in a cæcal extremity. Below, the fibrous layer is attached to the central tendon of the Diaphragm, and on the left side to its muscular fibres.

The vessels receiving fibrous prolongations from this membrane are the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmo-

nary veins. As the inferior vena cava enters the pericardium through the central tendon of the Diaphragm, it receives no covering from the *fibrous* layer.

The *serous layer* invests the heart, and is then reflected on the inner surface of the pericardium. It consists, therefore, of a visceral and parietal portion. The former invests the surface of the heart, and the commencement of the great vessels, to the extent of an inch and a half from their origin; from these it is reflected upon the inner surface of the fibrous layer, lining, below, the upper surface of the central tendon of the Diaphragm. The serous membrane encloses the aorta and pulmonary artery in a single tube, so that a passage, termed the *transverse sinus* of the pericardium, exists between these vessels in front and the auricles behind.

FIG. 275.—Front view of the thorax. The ribs and sternum are represented in relation to the lungs, heart, and other internal organs. 1. Pulmonary orifice. 2. Aortic orifice. 3. Left auriculo-ventricular orifice. 4. Right auriculo-ventricular orifice.

The membrane only partially covers the superior vena cava and the four pulmonary veins, and scarcely covers the inferior cava, as this vessel enters the heart almost directly after it has passed through the Diaphragm. Its inner surface is smooth and glistening, and secretes a serous fluid, which serves to facilitate the movements of the heart.

Arteries of the Pericardium.—These are derived from the internal mammary and its musculo-phrenic branch, and from the descending thoracic aorta.

Nerves of the Pericardium.—These are branches from the vagus, the phrenic, and the sympathetic.

The Vestigial Fold of the Pericardium.—Between the left pulmonary artery and subjacent pulmonary vein is a triangular fold of the serous pericardium; it is known

as the *vestigial fold of Marshall*. It is formed by the duplicature of the serous layer over the remnant of the lower part of the left superior cava (duct of Cuvier), which, after birth, becomes obliterated, and remains as a fibrous band stretching from the left superior intercostal vein to the left auricle, where it is continuous with a small vein, the oblique vein of Marshall, which opens into the coronary sinus.

Surgical Anatomy.—Paracentesis of the pericardium is sometimes required in cases of effusion into its cavity. The operation is best performed in the fifth intercostal space, one inch to the left of the sternum. The operation has been performed, however, in the fourth, sixth, and seventh spaces, and also on the right side of the sternum. Porter considers that by "reason of the uncertain and varying relations of the pleura, and also of the anterior position of the heart, whenever the pericardial sac is distended with fluid, aspiration of the pericardium is a much more dangerous procedure than open incision when done by skilled hands." He recommends that the operation should be done by resecting the fifth costal cartilage on the left side. By this means the surgeon avoids opening the pleural cavity, and secures continuous and free drainage, if the case is one of purulent pericarditis.

THE HEART.

The **Heart** is a hollow muscular organ of a conical form, placed between the lungs, and enclosed in the cavity of the pericardium.

Position.—The heart is placed obliquely in the chest: the broad attached end, or base, is directed upward, backward, and to the right, and corresponds with the dorsal vertebræ, from the fifth to the eighth inclusive; the apex is directed downward, forward, and to the left, and corresponds to the space between the cartilages of the fifth and sixth ribs, three-quarters of an inch to the inner side, and an inch and a half below the left nipple, or about three and a half inches from the middle line of the sternum. The heart is placed behind the lower two-thirds of the sternum, and projects farther into the left than into the right half of the cavity of the chest, extending from the median line about three inches in the former direction, and only one and a half in the latter; about one-third of the heart lies to the right and two-thirds to the left of the mesial plane. The anterior surface of the heart is round and convex, directed upward and forward, and formed chiefly by the right auricle and ventricle, together with a small part of the left ventricle. Its posterior surface, which looks downward rather than backward, is flattened and rests upon the Diaphragm, and is formed chiefly by the left ventricle. The right or lower border is long, thin, and sharp; the left or upper border short, but thick and round.

Size.—The heart, in the adult, measures five inches in length, three inches and a half in breadth in the broadest part, and two inches and a half in thickness. The prevalent weight, in the male, varies from ten to twelve ounces; in the female, from eight to ten: its proportions to the body being as 1 to 169 in males; 1 to 149 in females. The heart continues increasing in weight, and also in length, breadth, and thickness, up to an advanced period of life: this increase is more marked in men than in women.

Component Parts.—As has already been stated (page 455), the heart is subdivided by a muscular septum into two lateral halves, which are named respectively right and left; and a transverse constriction subdivides each half of the organ into two cavities, the upper cavity on each side being called the *auricle*, the lower the *ventricle*. The course of the blood through the heart cavities and blood-vessels has already been described (page 455).

The division of the heart into four cavities is indicated by grooves upon its surface. The groove separating the auricles from the ventricles is called the *auriculo-ventricular groove*. It is deficient, in front, where it is crossed by the root of the pulmonary artery. It contains the trunks of the nutrient vessels of the heart. The auricular portion occupies the base of the heart, and is subdivided into two cavities by a median septum. The two ventricles are also separated into a right and left by two furrows, the *interventricular grooves*, which are situated one on the anterior, the other on the posterior, surface; these extend from the base of the ventricular portion to near the apex of the organ; the former being situated

nearer to the left border of the heart, and the latter to the right. It follows, therefore, that the right ventricle forms the greater portion of the anterior surface of the heart, and the left ventricle more of its posterior surface.

Each of these cavities should now be separately examined.

The **Right Auricle** is a little larger than the left, its walls somewhat thinner, measuring about one line; and its cavity is capable of containing about two ounces. It consists of two parts: a principal cavity, the *sinus venosus*, or *atrium*, situated posteriorly, and an anterior, smaller portion, the *appendix auriculæ*.

FIG. 276.—The right auricle and ventricle laid open, the anterior walls of both being removed.

The *sinus* is the large quadrangular cavity, placed between the two venæ cavæ; its walls are extremely thin; it is connected below with the right ventricle, and internally with the left auricle, being free in the rest of its extent.

The *appendix auriculæ*, so called from its fancied resemblance to a dog's ear, is a small conical muscular pouch, the margins of which present a dentated edge. It projects from the sinus forward and to the left side, overlapping the root of the aorta.

To examine the interior of the right auricle, an incision should be made along its right border, from the entrance of the superior vena cava to that of the inferior. A second cut is to be made from the centre of this first incision to the tip of the auricular appendix, and the flaps raised.

The internal surface of the right auricle is smooth, except in the appendix and adjacent part of the anterior wall of the sinus venosus, where the muscular wall is thrown into parallel ridges resembling the teeth of a comb and hence named the *musculi pectinati*. These end behind on a vertical smooth ridge, the *crista terminalis* of His, the position of which is indicated on the surface of the distended auricle by a furrow, the *sulcus terminalis* (His); this represents the line of fusion of the sinus venosus of the embryo with the primitive auricle proper.

It presents the following parts for examination :

Openings	{	Superior cava.	Valves	{	Eustachian.
		Inferior cava.			Coronary.
		Coronary sinus.			
		Foramina Thebesii.			
		Auriculo-ventricular.			
		Fossa ovalis.			
		Annulus ovalis.			
		Tuberculum Loweri.			
		Musculi pectinati.			

The *superior vena cava* returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downward and forward.

The *inferior vena cava*, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the auricle near the septum, the direction of its orifice being upward and inward. The direction of a current of blood through the superior vena cava would consequently be toward the auriculo-ventricular orifice, whilst the direction of the blood through the inferior cava would be toward the auricular septum. This is the normal direction of the two currents in foetal life.

The *coronary sinus* opens into the auricle, between the inferior vena cava and the auriculo-ventricular opening. It returns the blood from the substance of the heart, and is protected by a semicircular fold of the lining membrane of the auricle, the *coronary valve* (*valve of Thebesius*). The sinus, before entering the auricle, is considerably dilated—nearly to the size of the end of the little finger. Its wall is partly muscular, and at its junction with the great coronary vein is somewhat constricted and furnished with a valve consisting of two unequal segments.

The *foramini Thebesii* are numerous minute apertures, the mouths of small veins (*venæ cordis minimæ*), which open on various parts of the inner surface of the auricle. They return the blood directly from the muscular substance of the heart. Some of these foramina are minute depressions in the walls of the heart, presenting a closed extremity.

The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and the ventricle, to be presently described.

The *Eustachian valve* is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. It is semilunar in form, its convex margin being attached to the wall of the vein; its concave margin, which is free, terminating in two cornua, of which the left is attached to the anterior edge of the annulus ovalis, the right being lost on the wall of the auricle. The valve is formed by a duplicature of the lining membrane of the auricle containing a few muscular fibres.

In the *fœtus* this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle.

In the *adult* it is occasionally persistent, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and its free margin presents a cribriform or filamentous appearance; occasionally it is altogether wanting.

The *coronary valve* (valve of Thebesius) is a semicircular fold of the lining membrane of the auricle, protecting the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve is occasionally double.

The *fossa ovalis* is an oval depression corresponding to the situation of the foramen ovale in the fœtus. It is situated at the lower part of the septum auricularum, above and to the left of the orifice of the inferior vena cava.

The *annulus ovalis* is the prominent oval margin of the foramen ovale. It is

most distinct above and at the sides; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa ovalis, which leads upward beneath the annulus into the left auricle, and is the remains of the aperture between the two auricles in the fœtus.

The *tuberculum Loweri* is a small projection on the right wall of the auricle, between the two venæ cavæ. It is most distinct in the hearts of quadrupeds; in man it is scarcely visible. It was supposed by Lower to direct the blood from the superior cava toward the auriculo-ventricular opening.

The **Right Ventricle** is triangular in form, and extends from the right auricle to near the apex of the heart. Its anterior or upper surface is rounded and convex, and forms the larger part of the front of the heart. Its under surface is flattened, rests upon the Diaphragm, and forms only a small part of the back of the heart. Its posterior wall is formed by the partition between the two ventricles, the *septum ventriculorum*, so that a transverse section of the cavity presents a semilunar outline. The surface of the septum is convex and bulges into the cavity of the right ventricle. Its upper and inner angle is prolonged into a conical pouch, the *infundibulum*, or *conus arteriosus*, from which the pulmonary artery arises. The walls of the right ventricle are thinner than those of the left, the proportion between them being as 1 to 3. The wall is thickest at the base, and gradually becomes thinner toward the apex. The cavity equals in size that of the left ventricle, and is capable of containing about three fluidounces.¹

To examine the interior of the right ventricle, its anterior wall should be turned downward and to the right in the form of a triangular flap. This is accomplished by making two incisions: (1) from the pulmonary artery to the apex of the ventricle parallel to, but a little to the right of, the anterior interventricular furrow; (2) another, starting from the upper extremity of the first and carried outward parallel to, but a little below, the auriculo-ventricular furrow, care being taken not to injure the auriculo-ventricular valve.

The following parts present themselves for examination:

Openings	{ Auriculo-ventricular.
	{ Opening of the pulmonary artery.
Valves	{ Tricuspid.
	{ Semilunar.

And a muscular and tendinous apparatus connected with the tricuspid valve:

Columnæ carneæ.

Chordæ tendineæ.

The *auriculo-ventricular orifice* is the large oval aperture of communication between the auricle and ventricle. It is situated at the base of the ventricle, near the right border of the heart. It is about an inch and a half in diameter,² oval from side to side, surrounded by a fibrous ring, covered by the lining membrane of the heart; it is considerably larger than the corresponding aperture on the left side, being sufficient to admit the ends of four fingers. It is guarded by the tricuspid valve.

The *opening of the pulmonary artery* is circular in form, and situated at the summit of the conus arteriosus, close to the septum ventriculorum. It is placed above and on the left side of the auriculo-ventricular opening, upon the anterior aspect of the heart. Its orifice is guarded by the pulmonary semilunar valves.

The *tricuspid valve* consists of three segments of a triangular or trapezoidal shape, formed by a duplicature of the lining membrane of the heart, strengthened by a layer of fibrous tissue, which contains, according to Kürschner and Senac,

¹ Marrant Baker says that "taking the mean of various estimates, it may be inferred that each ventricle is able to contain four to six ounces of blood" (Kirke's *Physiology*, 10th edition, p. 156).

² In the *Pathological Transactions*, vol. vi., p. 119, Dr. Peacock has given some careful researches upon the weight and dimensions of the heart in health and disease. He states, as the result of his investigations, that, in the healthy adult heart, the right auriculo-ventricular aperture has a mean circumference of 54.4 lines, or $4\frac{3}{4}$ inches; the left auriculo-ventricular aperture a mean circumference of 44.3 lines, or $3\frac{3}{4}$ inches; the pulmonic orifice of 40 lines, or $3\frac{1}{4}$ inches; and the aortic orifice of 35.5 lines, or $3\frac{1}{4}$ inches; but the dimensions of the orifices varied greatly in different cases, the right auriculo-ventricular aperture having a range of from 40 to 50 lines, and the others in the same proportion.

muscular fibres. These segments are connected by their bases to the fibrous ring surrounding the auriculo-ventricular orifice, and by their sides with one another, so as to form a continuous annular membrane, which is attached round the margin of the auriculo-ventricular opening, their free margins and ventricular surfaces affording attachment to a number of delicate tendinous cords, the *chordæ tendineæ*. The largest and most movable segment is placed toward the left side of the auriculo-ventricular opening, interposed between that opening and the infundibulum; hence it is called the *left* or *infundibular cusp*. Another segment corresponds to the right part of the front of the ventricle, the *right* or *marginal cusp*; and a third to its posterior wall, the *posterior* or *septal cusp*. The central part of each segment is thick and strong: the lateral margins are thin and translucent. The chordæ tendineæ are connected with the adjacent margins of the principal segments of the valve, and are further attached to each segment in the following manner: 1. Three or four reach the attached margin of each segment, where they are continuous with the auriculo-ventricular tendinous ring. 2. Others, four to six in number, are attached to the central thickened part of each segment. 3. The most numerous and finest are connected with the marginal portion of each segment.

The *columnæ carneæ* are the rounded muscular columns which project from nearly the whole of the inner surface of the ventricle, excepting near the opening of the pulmonary artery, where the wall is smooth. They may be classified, according to their mode of connection with the ventricle, into three sets. The first set merely form prominent ridges on the inner surface of the ventricle, being attached by their entire length on one side, as well as by their extremities. The second set are attached by their two extremities, but are free in the rest of their extent; while the third set (*musculi papillares*) are attached by one extremity to the wall of the heart, the opposite extremity giving attachment to the *chordæ tendineæ*. There are two papillary muscles, anterior and posterior: of these, the anterior is the larger; its chordæ tendineæ are connected with the right and left segments of the valve. The posterior is not always single, but sometimes consists of two or three muscular columns; its chordæ tendineæ are connected with the posterior and the right segments. In addition to these, some few chordæ may be seen springing directly from the ventricular septum, or from small eminences on it, and passing to the left and posterior segments. A fleshy band, well marked in the ox and some other animals, is frequently seen passing from the base of the anterior papillary muscle to the interventricular septum. From its attachments it may assist in preventing over-distention of the auricle, and so has been named the *moderator band*.

The right auriculo-ventricular orifice allows the blood to pass freely from the right auricle into the right ventricle, and it will be noted that the surface of the tricuspid valve next the blood-current is quite smooth. When the right ventricle contracts to force the blood into the pulmonary artery, the segments of the tricuspid valve come together and close the auriculo-ventricular opening, and so prevent the blood from passing back into the auricle. The papillary muscles and chordæ tendineæ moor the segments of the valve, and prevent their being forced through into the auricle by the weight of blood behind them.

The *semilunar valves*, three in number,¹ guard the orifice of the pulmonary artery. They consist of three semicircular folds, two anterior (right and left) and one posterior, formed by a duplicature of the lining membrane, strengthened by fibrous tissue. They are attached, by their convex margins, to the wall of the artery, at its junction with the ventricle, the straight border being free, and directed upward in the lumen of the vessel. The free margin of each is somewhat thicker than the rest of the valve, is strengthened by a bundle of tendinous fibres, and presents, at its middle, a small projecting thickened nodule, called *corpus Arantii*, and consisting of bundles of interlacing connective-tissue fibres with branched connective-tissue cells and some few elastic fibres. From this nodule

¹ The pulmonary semilunar valves have been found to be two in number instead of three (Dr. Hand, of St. Paul, Minn., in *North Western Med. and Surg. Journ.*, July, 1873), and the same variety is more frequently noticed in the aortic semilunar valves.

tendinous fibres radiate through the valve to its attached margin, and these fibres form a constituent part of its substance throughout its whole extent, excepting two narrow lunated portions, the *lunulæ*, placed one on each side of the nodule immediately adjoining the free margin; here the valve is thin, and formed merely by the lining membrane. During the passage of the blood along the pulmonary artery these valves are opened, and the course of the blood along the tube is uninterrupted; but during the ventricular diastole, when the current of blood along the pulmonary artery is checked and partly thrown back by its elastic walls, these valves become immediately expanded, and effectually close the entrance of the tube. When the valves are closed, the lunated portions of each are brought into contact with one another by their opposed surfaces, the three corpora Arantii filling up the small triangular space that would be otherwise left by the approximation of the three semilunar valves.

Between the semilunar valves and the commencement of the pulmonary artery are three pouches or dilatations, one behind each valve. These are the pulmonary sinuses (*sinuses of Valsalva*). Similar sinuses exist between the semilunar valves and the commencement of the aorta; they are larger than the pulmonary sinuses. The blood, in its regurgitation toward the heart, finds its way into these sinuses, and so shuts down the valve-flaps.

In order to examine the interior of the left auricle, make an incision on the posterior surface of the auricle from the pulmonary veins on one side to those on the other, the incision being carried a little way into the vessels. Make another incision from the middle of the horizontal one to the appendix.

The **Left Auricle** is rather smaller than the right; its walls thicker, measuring about one line and a half; it consists, like the right, of two parts, a principal cavity, or *sinus*, and an *appendix auriculæ*.

The *sinus* is cuboidal in form, and concealed in front by the pulmonary artery and aorta; internally, it is separated from the right auricle by the septum auricularum; behind, it receives on each side two pulmonary veins, being free in the rest of its extent.

The *appendix auriculæ* is somewhat constricted at its junction with the auricle; it is longer, narrower, and more curved than that of the right side, and its margins are more deeply indented, presenting a kind of foliated appearance. Its direction is forward and toward the right side, overlapping the root of the pulmonary artery.

Within the auricle the following parts present themselves for examination:

The openings of the four pulmonary veins.

Auriculo-ventricular opening.

Musculi pectinati.

The *pulmonary veins*, four in number, open, two into the right, and two into the left side of the auricle. The two left veins frequently terminate by a common opening. They are not provided with valves.

The *auriculo-ventricular opening* is the large oval aperture of communication between the auricle and ventricle. It is rather smaller than the corresponding opening on the opposite side (see note, page 463).

The *musculi pectinati* are fewer in number and smaller than on the right side; they are confined to the inner surface of the appendix.

On the inner surface of the septum auricularum may be seen a lunated impression bounded below by a crescentic ridge the concavity of which is turned upward. The depression is just above the fossa ovalis in the right auricle.

To examine the interior of the left ventricle, make an incision a little to the left of the anterior interventricular groove from the base to the apex of the heart, and carry it up from thence, a little to the left of the posterior interventricular groove, nearly as far as the auriculo-ventricular groove.

The **Left Ventricle** is longer and more conical in shape than the right ventricle, and on transverse section its cavity presents an oval or nearly circular outline. It forms a small part of the anterior surface of the heart, and a considerable part of

its posterior surface. It also forms the apex of the heart by its projection beyond the right ventricle. Its walls are much thicker than those of the right side, the proportion being as 3 to 1. They are thickest opposite the widest part of the ventricle, becoming gradually thinner toward the base, and also toward the apex, which is the thinnest part.

The following parts present themselves for examination :

Openings { Auriculo-ventricular.
Aortic.
Chordæ tendineæ.

Valves { Mitral.
Semilunar.
Columnæ carneæ.

The *auriculo-ventricular opening* is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side,

FIG. 277.—The left auricle and ventricle laid open, the posterior walls of both being removed.

admitting only two fingers ; but, like it, is broader in the transverse than in the antero-posterior diameter. It is surrounded by a dense fibrous ring, covered by the lining membrane of the heart, and guarded by the mitral valves.

The *aortic opening* is a circular aperture, in front and to the right side of the auriculo-ventricular, from which it is separated by one of the segments of the mitral valve. Its orifice is guarded by the semilunar valves. The portion of the ventricle immediately below the aortic orifice is often termed the *aortic vestibule* of Sibson. It possesses fibrous instead of muscular walls, and so does not collapse during the ventricular diastole ; it thus gives space for the segments of the aortic valve during its closure.

The *mitral valve* is attached to the circumference of the auriculo-ventricular orifice in the same way that the tricuspid valve is on the opposite side. It is formed by a duplicature of the lining membrane, strengthened by fibrous tissue, and contains a few muscular fibres. It is larger in size, thicker, and altogether stronger than the tricuspid, and consists of two segments of unequal size. The larger segment is placed in front and to the right between the auriculo-ventricular

and aortic orifices, the smaller to the left and behind the opening, close to the wall of the ventricle. Two smaller segments are usually found at the angles of junction of the larger. The mitral valve-flaps are furnished with chordæ tendineæ, the mode of attachment of which is precisely similar to those on the right side; but they are thicker, stronger, and less numerous.

The *semilunar valves* surround the orifice of the aorta; two are posterior (right and left) and one anterior: they are similar in structure and in their mode of attachment to those of the pulmonary artery. They are, however, larger, thicker, and stronger than those of the right side; the lunulæ are more distinct, and the corpora Arantii larger and more prominent. Opposite each segment the wall of the aorta presents a slight dilatation or bulging (*sinus of Valsalva*). They are larger than those at the commencement of the pulmonary artery.

FIG. 278.—Section of the heart, showing the interventricular septum.

The *columnæ carneæ* admit of a subdivision into three sets, like those upon the right side; but they are smaller, more numerous, and present a dense interlacement, especially at the apex, and upon the posterior wall. Those attached by one extremity only, the *musculi papillares*, are two in number, being connected one to the anterior, the other to the posterior wall; they are of large size, and terminate by free rounded extremities, from which the chordæ tendineæ arise.

The septum between the two ventricles is thick, especially below (Fig. 278). At its upper part it suddenly tapers off and becomes destitute of muscular fibres, consisting only of fibrous tissue, covered by two layers of endocardium; and on the right side also covered, during diastole, by one of the flaps of the tricuspid valve. This upper portion is termed the *membranous part* of the septum, and is continued upward and forms the septum between the aortic vestibule and the right

auricle. It is derived from the lower part of the aortic septum of the fœtus, and an abnormal communication may exist at this part, owing to defective development of this septum.

The *Endocardium* is a thin membrane which lines the internal surface of the heart; it assists in forming the valves by its reduplications, and is continuous with the lining membrane of the great blood-vessels. It is a smooth, transparent membrane, giving to the inner surface of the heart its glistening appearance. It is more opaque on the left than on the right side of the heart, thicker in the auricles than in the ventricles; and thickest in the left auricle. It is thin on the muscoli pectinati and on the columæ carneæ, but thicker on the smooth part of the auricular and ventricular walls and on the tips of the muscoli papillares.

Structure.—The heart consists of muscular fibres, and of fibrous rings which serve for their attachment. It is closely covered by the visceral layer of the serous pericardium (*epicardium*), and its cavities are lined by the *endocardium*. Between these two membranes is the muscular wall of the heart, the *myocardium*.

The *fibrous rings* surround the auriculo-ventricular and arterial orifices; they are stronger upon the left than on the right side of the heart. The auriculo-ventricular rings serve for the attachment of the muscular fibres of the auricles and ventricles, and also for the mitral and tricuspid valves; the ring on the left side is closely connected by its right margin with the aortic arterial ring. Between these and the right auriculo-ventricular ring is a mass of fibrous tissue, and in some of the larger animals, as the ox and elephant, a nodule of bone, the *os cordis*.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, within which the middle coat of the artery (which presents three convex semicircular segments) is firmly fixed, the attachment of the artery to its fibrous ring being strengthened by the thin cellular coat and serous membrane externally and by the endocardium within. It is opposite the margins of these semicircular notches, in the arterial rings, that the endocardium by its reduplication, forms the semilunar valves, the fibrous structure of the ring being continued into each of the segments of the valve at this part. The middle coat of the artery in this situation is thin, and the sides of the vessel are dilated to form the sinuses of Valsalva.

The *muscular structure of the heart* consists of bands of fibres which present an exceedingly intricate interlacement. They are of a deep red color and marked with transverse striæ.

The muscular fibres of the heart admit of a subdivision into two groups, those of the auricles and those of the ventricles, which are quite independent of one another.

Fibres of the Auricles.—These are disposed in two layers—a superficial layer common to both cavities, and a deep layer proper to each. The *superficial fibres* are more distinct on the anterior surface of the auricles, across the bases of which they run in a transverse direction, forming a thin, but incomplete layer. Some of these fibres pass into the septum auricularum. The *internal* or *deep fibres* proper to each auricle consist of two sets, looped and annular fibres. The *looped fibres* pass upward over each auricle, being attached by two extremities to the corresponding auriculo-ventricular rings in front and behind. The *annular fibres* surround the whole extent of the appendices auricularum, and are continued upon the walls of the venæ cavæ and coronary sinus on the right side, and upon the pulmonary veins on the left side, at their connection with the heart. In the appendices they interlace with the longitudinal fibres.

Fibres of the Ventricles.—These are arranged in an exceedingly complex manner, and the accounts given by various anatomists differ considerably. This is probably due partly to the fact that the various layers of muscular fibres of which the heart is said to be composed are not independent, but their fibres are interlaced to a considerable extent, and therefore any separation into layers must be to a great extent artificial; and also partly to the fact, pointed out by Henle, that

there are varieties in the arrangement due to individual differences. If the *epicardium* and the subjacent fat are removed from a heart which has been subjected to prolonged boiling, so as to dissolve the connective tissues, the superficial fibres of the ventricles will be exposed. They will be seen to commence at the base of the heart, where they are attached to the tendinous rings around the orifices, and to pass obliquely downward toward the apex, with a direction from right to left. At the apex the fibres turn suddenly inward into the interior of the ventricle, forming what is called the *vortex*. On the back of the heart it will be seen that the fibres pass continuously from one ventricle to the other over the interventricular groove; and the same thing will be noticed on the front of the heart at the upper and lower end of the anterior interventricular groove, but in the middle portion of this groove the fibres passing from one ventricle to the other are interrupted by fibres emerging from the septum along the groove; many of the superficial fibres pass in also at this groove to the septum. The vortex is produced, as stated above, by the sudden turning inward of the superficial fibres in a peculiar spiral manner into the interior of the ventricle. Those fibres which descended on the posterior surface of the heart enter the left ventricle at the vortex, and, ascending, form the posterior part of the inner layer of muscular fibres lining this cavity and the right (posterior) *musculus papillaris*; those fibres which descend on the front of the heart to reach the apex also pass, at the vortex, into the interior of the ventricle, where they form the remainder of the innermost layer of the ventricle and the left (anterior) *musculus papillaris*. The fibres forming the inner layer of the wall of the ventricle ascend to be attached to the fibrous rings around the orifices.

By dissection these superficial fibres may be removed as a thin stratum, and it will then be found that the ventricles are made up of oblique fibres superimposed in layers one on the top of another, and assuming gradually a less oblique direction as they pass to the middle of the thickness of the ventricular wall, so that in the centre of the wall the fibres are transverse. Internal to this central transverse layer the fibres become oblique again, but in the opposite direction to the external ones. This division into distinct layers is, however, to a great extent artificial, as the fibres pass across from one layer to another, and have therefore to be divided in the dissection, and the change in the direction of the fibres is very gradual. These oblique fibres commence above at the fibrous rings at the base of the heart, and, descending toward the apex, they enter the septum near its lower end. In the septum the fibres which form the left ventricle may be traced in three directions: 1. Some pass upward to be attached to the central mass of fibrous tissue. 2. Others pass through the septum to become continuous with the fibres of the right ventricle. 3. The remainder pass through the septum to encircle the ventricle as annular fibres. Of the fibres of the right ventricle, some on entering the septum pass upward to be attached to the central mass of fibrous tissue; some, entering the septum from behind, pass forward to become continuous with the fibres on the anterior surface of the left ventricle; and others, entering in front, pass backward to join the fibres on the posterior wall of the left ventricle. The septum therefore consists of three varieties of fibres—viz., annular fibres, special to the left ventricle; ascending fibres, derived from both ventricles and ascending through the septum to the central fibro-cartilage; and decussating fibres, derived from the anterior wall of one ventricle and passing to the posterior wall of the other ventricle, or from the posterior wall of the right ventricle and passing to the anterior wall of the left. In addition to these fibres there are a considerable number which appear to encircle both ventricles and which pass across the septum without turning into it.

Vessels and Nerves.—The *arteries* supplying the heart are the right and left coronary from the aorta.

The *veins* accompany the arteries, and terminate in the right auricle. They are, the anterior or great, posterior, left and anterior cardiac veins, the right or small, and the left or great, coronary sinuses and the *venæ Thebesii* (*venæ cordis minimæ*).

The *lymphatics* terminate in the thoracic and right lymphatic ducts.

The *nerves* are derived from the cardiac plexuses, which are formed partly from the cranial nerves and partly from the sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia.

Surface Form.—In order to show the extent of the heart in relation to the front of the chest, draw a line from the lower border of the second left costal cartilage, one inch from the sternum, to the upper border of the third right costal cartilage, half an inch from the sternum. This represents the base-line or upper limit of the organ. Take a point an inch and a half below and three-quarters of an inch internal to the left nipple—that is, about three and a half inches to the left of the median line of the body. This represents the apex of the heart. Draw a line from this apex-point, with a slight convexity downward, to the junction of the seventh right costal cartilage to the sternum. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base-line—with the right extremity of this line—that is, to the seventh right chondro-sternal joint—with a slight curve outward, so that it projects about an inch and a half from the middle line of the sternum. Lastly, join the left extremity of the base-line and the apex-point by a line curved slightly to the left.

The position of the various orifices is as follows: viz. the pulmonary orifice is situated in the upper angle formed by the articulation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the articulation of the third left costal cartilage to this bone. The left auriculo-ventricular opening is behind the sternum, rather to the left of the median line, and opposite the fourth costal cartilages. The right auriculo-ventricular opening is a little lower, opposite the fourth interspace and in the middle line of the body (Fig. 275).

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the area of superficial cardiac dullness; the latter as the area of deep cardiac dullness. The area of superficial cardiac dullness is included between a line drawn from the centre of the sternum, on a level with the fourth costal cartilages, to the apex of the heart and a line drawn from the same point down the lower third of the middle line of the sternum. Below, this area merges into the dullness which corresponds to the liver. Dr. Latham lays down the following rule as a sufficient practical guide for the definition of the portion of the heart which is uncovered by lung or pleura: "Make a circle of two inches in diameter round a point midway between the nipple and the end of the sternum."

Surgical Anatomy.—Wounds of the heart are often immediately fatal, but not necessarily so. They may be non-penetrating, when death may occur from hemorrhage, if one of the coronary vessels has been wounded, or subsequently from pericarditis; or, on the other hand, the patient may recover. Even a penetrating wound is not necessarily fatal, if the wound is a small one. A flap comprising the whole thickness of the thoracic wall may be made, the cavity of the pericardium opened, and the wound in the heart sutured. This has been done successfully.

Peculiarities in the Vascular System of the Fœtus.

The chief peculiarities in the heart of the fœtus are the direct communication between the two auricles through the foramen ovale and the large size of the Eustachian valve. There are also several minor peculiarities. Thus, the position of the heart is vertical until the fourth month, when it commences to assume an oblique direction. Its size is also very considerable as compared with the body, the proportion at the second month being 1 to 50; at birth it is as 1 to 120; whilst in the adult the average is about 1 to 160. At an early period of fœtal life the auricular portion of the heart is larger than the ventricular, the right auricle being more capacious than the left; but toward birth the ventricular portion becomes the larger. The thickness of both ventricles is at first about equal, but toward birth the left becomes much the thicker of the two.

The *foramen ovale* is situated at the lower and back part of the septum auricularum, forming a communication between the auricles. It remains as a free oval opening until the middle period of fœtal life. About this period a fold grows up from the posterior wall of the auricle to the left of the foramen ovale, and advances over the opening so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, and not in the opposite direction.

The *Eustachian valve* is directed upward on the left side of the opening of the inferior vena cava, and serves to direct the blood from this vessel through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fœtus are the communication between the pulmonary artery and the descending aorta by means of the *ductus*

arteriosus, and the communication between the internal iliac arteries and the placenta by means of the umbilical arteries.

The *ductus arteriosus* is a short tube, about half an inch in length at birth, and of the diameter of a goosequill. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta just below the origin of the left subclavian artery, and so conducts the chief part of the blood from the right ventricle into this vessel. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord, which is all that remains of the ductus arteriosus in later life, will be found to be attached to the root of that vessel.

The *umbilical* or *hypogastric arteries* arise from the internal iliacs, in addition to the branches given off from those vessels in the adult. Ascending along the sides of the bladder to its apex, they pass out of the abdomen at the umbilicus and are continued along the umbilical cord to the placenta, coiling round the umbilical vein. They carry to the placenta the blood which has circulated in the system of the foetus.

The peculiarity in the venous system of the foetus is the communication established between the placenta and the liver and portal vein through the umbilical vein, and the inferior vena cava through the ductus venosus.

FŒTAL CIRCULATION.

The blood destined for the nutrition of the foetus is returned from the placenta to the foetus by the umbilical vein. This vein enters the abdomen at the umbilicus, and passes upward along the free margin of the suspensory ligament of the liver to the under surface of that organ, where it gives off two or three branches to the left lobe, one of which is of large size, and others to the lobus quadratus and lobulus Spigelii. At the transverse fissure it divides into two branches: of these, the larger is joined by the portal vein and enters the right lobe; the smaller branch continues outward, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein reaches the inferior vena cava in three different ways: the greater quantity circulates through the liver with the portal venous blood before entering the vena cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior cava by the hepatic veins; the smaller quantity passes directly into the vena cava by the junction of the ductus venosus with the left hepatic vein.

In the inferior cava the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and wall of the abdomen. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it becomes mixed with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle, and from the left ventricle into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the tributaries of the superior vena cava to the right auricle, where it becomes mixed with a small portion of the blood from the inferior cava. From the right auricle it descends over the Eustachian valve into the right ventricle, and from the right ventricle passes into the pulmonary artery. The lungs of the foetus being inactive, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and is returned by the pulmonary veins to the left auricle; the greater part passes through the ductus arteriosus into the commencement of the descending aorta, where it becomes mixed with a small quantity of blood transmitted by the left ventricle into the aorta. Through

this vessel it descends to supply the lower extremities and viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fœtus it will be seen—

1. That the placenta serves the purposes of nutrition and excretion, receiving

FIG. 279.—Plan of the foetal circulation. In this plan the figured arrows represent the kind of blood, as well as the direction which it takes in the vessels. Thus, arterial blood is figured $\rightarrow \cdots \cdots \rightarrow$; venous blood, $\rightarrow \cdots \cdots \rightarrow$; mixed (arterial and venous) blood, $\rightarrow \cdots \cdots \rightarrow$.

the impure blood from the foetus, and returning it charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver

before entering the inferior cava; hence the large size of this organ, especially at an early period of foetal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior cava being guided by the Eustachian valve into the left auricle, whilst that in the superior cava descends into the right ventricle. At an early period of foetal life it is highly probable that the two streams are quite distinct, for the inferior cava opens almost directly into the left auricle, and the Eustachian valve would exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems probable that some mixture of the two streams must take place.

4. The pure blood carried from the placenta to the foetus by the umbilical vein, mixed with the blood from the portal vein and inferior cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities; hence the large size and perfect development of those parts at birth.

5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and upper limbs, together with a small quantity from the left ventricle, is distributed to the lower extremities; hence the small size and imperfect development of these parts at birth.

CHANGES IN THE VASCULAR SYSTEM AT BIRTH.

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, which now perform their office as respiratory organs, and at the same time the placental circulation is cut off. The foramen ovale becomes gradually closed by about the tenth day after birth; the valvular fold above mentioned becomes adherent to the margins of the foramen for the greater part of its circumference, but above a slit-like opening is left between the two auricles which sometimes remains persistent.

The *ductus arteriosus* begins to contract immediately after respiration is established, becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord which serves to connect the left pulmonary artery to the descending aorta.

Of the *umbilical* or *hypogastric arteries*, the portion continued on to the bladder from the trunk of the corresponding internal iliac remains pervious as the superior vesical artery, and the part extending from the side of the bladder to the umbilicus becomes obliterated between the second and fifth days after birth, and projects as a fibrous cord toward the abdominal cavity, carrying on it a fold of peritoneum and separating two of the fossæ of the peritoneum spoken of in the section on the surgical anatomy of direct inguinal hernia.

The *umbilical vein* and *ductus venosus* become completely obliterated between the second and fifth days after birth, and ultimately dwindle to fibrous cords, the former becoming the round ligament of the liver, the latter the fibrous cord, which in the adult may be traced along the fissure of the ductus venosus.

THE ARTERIES.

THE Arteries are cylindrical tubular vessels which serve to convey blood from both ventricles of the heart to every part of the body. These vessels were named arteries (*ἀήρ*, air; *τηρεῖν*, to contain) from the belief entertained by the ancients that they contained air. To Galen is due the honor of refuting this opinion; he showed that these vessels, though for the most part empty after death, contain blood in the living body.

The distribution of the systemic arteries is like a highly ramified tree, the common trunk of which, formed by the aorta, commences at the left ventricle of the heart, the smallest ramifications corresponding to the circumference of the body and the contained organs. The arteries are found in nearly every part of the body, with the exception of the hairs, nails, epidermis, cartilages, and cornea; and the larger trunks usually occupy the most protected situations, running, in the limbs, along the flexor side, where they are less exposed to injury.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as we observe in the celiac and thyroid axes; or the vessel may give off several branches in succession, and still continue as the main trunk, as is seen in the arteries of the limbs; but the usual division is dichotomous; as, for instance, the aorta dividing into the two common iliacs, and the common carotid into the external and internal.

The branches of arteries arise at very variable angles: some, as the superior intercostal arteries from the aorta, arise at an obtuse angle: others, as the lumbar arteries, at a right angle; or, as the spermatic, at an acute angle. An artery from which a branch is given off is smaller in size, but retains a uniform diameter until a second branch is derived from it. A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk; and the combined area of all the arterial branches greatly exceeds the area of the aorta; so that the arteries collectively may be regarded as a cone, the apex of which corresponds to the aorta, the base to the capillary system.

The arteries, in their distribution, communicate with one another, forming what is called an *anastomosis* (*ἀνά*, between; *στόμα*, mouth), or inosculation; and this communication is very free between the large as well as between the smaller branches. The anastomosis between trunks of equal size is found where great activity of the circulation is requisite, as in the brain; here the two vertebral arteries unite to form the basilar, and the two internal carotid arteries are connected by a short communicating trunk; it is also found in the abdomen, the intestinal arteries having very ample anastomoses between their larger branches. In the limbs the anastomoses are most numerous and of largest size around the joints, the branches of an artery above inosculating with branches from the vessels below; these anastomoses are of considerable interest to the surgeon, as it is by their enlargement that a *collateral circulation* is established after the application of a ligature to an artery for the cure of aneurism. The smaller branches of arteries anastomose more frequently than the larger, and between the smallest twigs these inosculations become so numerous as to constitute a close network that pervades nearly every tissue of the body.

Throughout the body generally the larger arterial branches pursue a perfectly straight course, but in certain situations they are tortuous; thus, the facial artery in its course over the face, and the arteries of the lips, are extremely tortuous in their course, to accommodate themselves to the movements of the parts. The

uterine arteries are also tortuous, to accommodate themselves to the increase of size which the organ undergoes during pregnancy. Again, the internal carotid and vertebral arteries, previous to their entering the cavity of the skull, describe a series of curves, which are evidently intended to diminish the velocity of the current of blood by increasing the extent of surface over which it moves and adding to the amount of impediment which is produced by friction.

The arteries are dense in structure, of considerable strength, highly elastic, and, when divided, they preserve, although empty, their cylindrical form.

The minute structure of these vessels has been described in the chapter on General Anatomy.

In the description of the arteries we shall first consider the efferent trunk of the pulmonic circulation, the pulmonary artery, and then the efferent trunk of the systemic circulation, the aorta and its branches.

PULMONARY ARTERY (Fig. 280).

The **Pulmonary Artery** conveys the venous blood from the right side of the heart to the lungs. It is a short, wide vessel, about 2 inches in length and $1\frac{1}{2}$ inches (30 mm.) in diameter, arising from the left side of the base (conus arteriosus) of the right ventricle, in front of the aorta. It extends obliquely upward and backward, passing at first in front of and then to the left of the ascending aorta, as far as the under surface of the arch, where it divides, about on a level with the intervertebral substance between the fifth and sixth dorsal vertebrae, into two branches of nearly equal size, the *right* and *left pulmonary arteries*.

Relations.—The whole of this vessel is contained, together with the ascending aorta, in the pericardium. It is enclosed with the aorta in a single tube of the serous pericardium, which is continued upward upon them from the base of the heart and connects them together. The fibrous layer of the pericardium becomes gradually lost upon the external coat of its two branches. In front, the pulmonary artery is separated from the anterior extremity of the second left intercostal space by the pleura and left lung, in addition to the pericardium; it rests at first upon the ascending aorta, and higher up lies in front of the left auricle on a plane posterior to the ascending aorta. On each side of its origin is the appendix of the corresponding auricle and a coronary artery, the left coronary artery passing, in the first part of its course, behind the vessel.

The **right pulmonary artery**, longer and larger than the left, runs horizontally outward, behind the ascending aorta and superior vena cava, to the root of the right lung, where it divides into two branches, of which the lower and larger supplies the middle and lower lobes; the upper and smaller is distributed to the upper lobe.

The **left pulmonary artery**, shorter and somewhat smaller than the right, passes horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches for the two lobes.

The root of the left pulmonary artery is connected to the under surface of the arch of the aorta by a short fibrous cord, the *ligamentum arteriosum*; this is the remains of a vessel peculiar to foetal life, the *ductus arteriosus*.

The terminal branches of the pulmonary artery will be described with the anatomy of the lung.

THE AORTA.

The **aorta** (*ἀορτή*, arteria magna) is the main trunk of a series of vessels which convey the oxygenated blood to the tissues of the body for their nutrition. This vessel commences at the upper part of the left ventricle, where it is about one and one-eighth inches in diameter, and, after ascending for a short distance, arches backward and to the left side, over the root of the left lung, then descends within the thorax on the left side of the vertebral column, passes through the aortic opening in the Diaphragm, and, entering the abdominal cavity, terminates, considerably diminished in size (about seven-tenths of an inch in diameter), opposite the lower border of the fourth lumbar vertebra, where it divides into the right and left common iliac arteries. Hence it is divided into the *ascending aorta*, the *arch of*

the aorta, and the *descending aorta*, which last is again divided into *thoracic aorta* and *abdominal aorta*, from the position of these parts.

THE ASCENDING AORTA.

The *ascending aorta* is about two inches in length. It commences at the upper part of the left ventricle, on a level with the lower border of the third costal cartilage, behind the left half of the sternum; it passes obliquely upward, forward, and to the right, in the direction of the heart's axis, as high as the upper border of the

FIG. 280.—The arch of the aorta and its branches.

FIG. 281.—Plan of the branches.

second right costal cartilage, describing a slight curve in its course, and being situated, when distended, about a quarter of an inch behind the posterior surface of the sternum. A little above its commencement it is somewhat enlarged, and presents three small dilatations, called the sinuses of Valsalva, opposite to which are attached the three semilunar valves, which serve the purpose of preventing any regurgitation of blood into the cavity of the ventricle. These valves are placed one in front and two behind. At the union of the ascending with the transverse part of the aorta the calibre of the vessel is increased, owing to a bulging outward of its right wall. This dilatation is termed the *great sinus of the aorta*. A section of the aorta

opposite this part has a somewhat oval figure; but below the attachment of the valves it is circular. This portion of the aorta is contained in the cavity of the pericardium, and, together with the pulmonary artery, is invested in a tube of serous membrane, continued on to them from the surface of the heart.

Relations.—The ascending aorta is covered at its commencement by the trunk of the pulmonary artery and the right auricular appendix, and, higher up, is separated from the sternum by the pericardium, the right pleura, and anterior margin of right lung, some loose areolar tissue, and the remains of the thymus gland; *behind*, it rests upon the right pulmonary artery and left auricle. On the *right side* it is in relation with the superior vena cava and right auricle; on the *left side*, with the pulmonary artery.

PLAN OF THE RELATIONS OF THE ASCENDING AORTA.

BRANCHES OF THE ASCENDING AORTA.

The only branches of the ascending aorta are the coronary arteries. They supply the heart, and are two in number, right and left, arising near the commencement of the aorta, immediately above the free margin of the semilunar valves.

THE CORONARY ARTERIES.

The **Right Coronary Artery**, about the size of a crow's quill, arises from the anterior sinus of Valsalva. It passes forward between the pulmonary artery and the right auricular appendix, then runs obliquely to the right side, in the groove between the right auricle and ventricle, and, curving around the right border of the heart, runs along its posterior surface as far as the posterior interventricular groove, where it divides into two branches, one of which (*transverse*) continues onward in the groove between the left auricle and ventricle, and anastomoses with the left coronary; the other (*descending*) courses along the posterior interventricular furrow, supplying branches to both ventricles and to the septum, and anastomosing at the apex of the heart with the descending branches of the left coronary.

This vessel sends a large branch (*marginal*) along the thin margin of the right ventricle to the apex, which in its course gives off numerous small branches to the anterior and posterior surfaces of the ventricle. It also gives off a branch (*infundibular*) which ramifies over the front part of the conus arteriosus of the right ventricle.

The **Left Coronary**, larger than the former, arises from the left posterior sinus of Valsalva; it passes forward between the pulmonary artery and the left auricular appendix, and divides into two branches. Of these, one (*transverse*) passes transversely outward in the left auriculo-ventricular groove, and winds around the left border of the heart to its posterior surface, where it anastomoses with the trans-

verse branch of the right coronary; the other (*descending*) passes along the anterior interventricular groove to the apex of the heart, where it anastomoses with the descending branches of the right coronary. The left coronary supplies the left auricle and its appendix, gives branches to both ventricles, and numerous small branches to the pulmonary artery and commencement of the aorta.¹

Peculiarities.—These vessels occasionally arise by a common trunk, or their number may be increased to three, the additional branch being of small size. More rarely there are two additional branches.

THE ARCH OF THE AORTA.

The **arch**, or **transverse aorta**, commences at the upper border of the second chondro-sternal articulation of the right side, and passes at first upward and backward and from right to left, and then from before backward, to the left side of the lower border of the fourth dorsal vertebra behind. Its upper border is usually about an inch below the upper margin of the sternum.

Between the origin of the left subclavian artery and the attachment of the ductus arteriosus the lumen of the foetal aorta is considerably narrowed, forming what is termed the *aortic isthmus*, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation which His has named the *aortic spindle*—the point of junction of the two parts being marked in the concavity of the arch by an indentation or angle. These conditions persist, to some extent, in the adult, where His found that the average diameter of the spindle exceeded that of the isthmus by 3 mm. (about one-eighth of an inch).

Relations.—Its *anterior surface* is covered by the pleuræ and lungs and the remains of the thymus gland, and crossed toward the left side by the left pneumogastric and phrenic nerves and superficial cardiac branches of the left sympathetic and vagus, and by the left superior intercostal vein. Its *posterior surface* lies on the trachea, just above its bifurcation, on the great, or deep, cardiac plexus, the œsophagus, thoracic duct, and left recurrent laryngeal nerve. Its *upper border* is in relation with the left innominate vein, and from its upper part are given off the innominate, left common carotid and left subclavian arteries. Its *lower border* is in relation with the bifurcation of the pulmonary artery, the remains of the ductus arteriosus, which is connected with the left division of that vessel, and the superficial cardiac plexus; the left recurrent laryngeal nerve winds round it from before backward, whilst the left bronchus passes below it.

PLAN OF THE RELATIONS OF THE ARCH OF THE AORTA.

¹ According to Dr. Samuel West, there is a very free and complete anastomosis between the two coronary arteries (*Lancet*, June 2, 1883, p. 945). This, however, is not the view generally held by anatomists, for, with the exception of the anastomosis mentioned above in the auriculo-ventricular and interventricular grooves, it is believed that the two arteries only communicate by very small vessels in the substance of the heart.

Peculiarities.—The height to which the aorta rises in the chest is usually about an inch below the upper border of the sternum; but it may ascend nearly to the top of that bone. Occasionally it is found an inch and a half, more rarely two or even three inches, below this point.

In Direction.—Sometimes the aorta arches over the root of the right instead of the left lung, as in birds, and passes down on the right side of the spine. In such cases all of the viscera of the thoracic and abdominal cavities are transposed. Less frequently, the aorta, after arching over the root of the right lung, is directed to its usual position on the left side of the spine, this peculiarity not being accompanied by any transposition of the viscera.

In Conformation.—The aorta occasionally divides, as in some quadrupeds, into an ascending and descending trunk, the former of which is directed vertically upward, and subdivides into three branches, to supply the head and upper extremities. Sometimes the aorta subdivides soon after its origin into two branches, which soon reunite. In one of these cases the œsophagus and trachea were found to pass through the interval left by their division; this is the normal condition of the vessel in the reptilia.

Surgical Anatomy.—Of all the vessels of the arterial system, the aorta, and more especially its arch, is most frequently the seat of disease; hence it is important to consider some of the consequences that may ensue from aneurism of this part.

It will be remembered that the ascending aorta is contained in the pericardium, just behind the sternum, being crossed at its commencement by the pulmonary artery and right auricular appendix, and having the right pulmonary artery behind, the vena cava on the right side, and the pulmonary artery and left auricle on the left side.

Aneurism of the ascending aorta, in the situation of the sinuses of Valsalva, in the great majority of cases, affects the anterior sinus; this is mainly owing to the fact that the regurgita-

FIG. 282.—Relation of great vessels at base of heart, seen from above. (From a preparation in the Museum of the Royal College of Surgeons of England.)

tion of blood upon the sinuses takes place chiefly on the anterior aspect of the vessel. As the aneurismal sac enlarges it may compress any or all of the structures in immediate proximity with it, but chiefly projects toward the right anterior side, and, consequently, interferes mainly with those structures that have a corresponding relation with the vessel. In the majority of cases it bursts into the cavity of the pericardium, the patient suddenly drops down dead, and, upon a post-mortem examination, the pericardial sac is found full of blood; or it may compress the right auricle, or the pulmonary artery and adjoining part of the right ventricle, and open into one or the other of these parts, or may press upon the superior vena cava.

Aneurism of the ascending aorta, originating above the sinuses, most frequently implicates the right anterior wall of the vessel, where, as has been explained, there exists a normal dilatation, the great sinus of the aorta; this is probably mainly owing to the blood being impelled against this part. The direction of the aneurism is also chiefly toward the right of the median line. If it attains a large size and projects forward, it may absorb the sternum and the cartilages of the ribs, usually on the right side, and appear as a pulsating tumor on the front of the chest, just below the manubrium; or it may burst into the pericardium, or may compress or open into the right lung, the trachea, bronchi, or œsophagus.

Regarding the transverse aorta, the student is reminded that the vessel lies on the trachea, the œsophagus, and thoracic duct; that the recurrent laryngeal nerve winds around it; and that from its upper part are given off three large trunks, which supply the head, neck, and upper extremities. Now, an aneurismal tumor, taking origin from the posterior part of the vessel, its most usual site, may press upon the trachea, impede the breathing, or produce cough, hæmoptysis, or stridulous breathing, or it may ultimately burst into that tube, producing fatal hemorrhage. Again, its pressure on the laryngeal nerves may give rise to symptoms which so accurately resemble those of laryngitis that the operation of tracheotomy has in some cases been resorted to, from the supposition that disease existed in the larynx; or it may press upon the thoracic duct and destroy life by inanition; or it may involve the œsophagus, producing dysphagia; or may burst into the œsophagus, when fatal hæmorrhage will occur. Again, the innominate artery, or the subclavian, or left carotid, may be so obstructed by clots as to produce a weakness, or even a disappearance, of the pulse in one or the other wrist or in the left temporal artery; or the tumor may present itself at or above the manubrium, generally either in the median line or to the right of the sternum, and may simulate an aneurism of one of the arteries of the neck.

BRANCHES OF THE ARCH OF THE AORTA (Figs. 280, 281).

The branches given off from the arch of the aorta are three in number: the innominate artery, the left common carotid, and the left subclavian.

Peculiarities.—Position of the Branches.—The branches, instead of arising from the highest part of the arch (their usual position), may be moved more to the right, arising from the commencement of the transverse or upper part of the ascending portion: or the distance from one another at their origin may be increased or diminished, the most frequent change in this respect being the approximation of the left carotid toward the innominate artery.

The Number of the primary branches may be reduced to a single vessel, or more commonly two: the left carotid arising from the innominate artery, or (more rarely) the carotid and subclavian arteries of the left side arising from a left innominate artery. But the number may be increased to four, from the right carotid and subclavian arteries arising directly from the aorta, the innominate being absent. In most of these latter cases the right subclavian has been found to arise from the left end of the arch; in other cases it was the second or third branch given off instead of the first. Another common form in which there are four primary branches is that in which the left vertebral artery arises from the arch of the aorta between the left carotid and subclavian arteries. Lastly, the number of trunks from the arch may be increased to five or six; in these instances, the external and internal carotids arise separately from the arch, the common carotid being absent on one or both sides. In some cases, where six branches have been found, it has been due to a separate origin of the vertebral on both sides.

Number Usual, Arrangement Different.—When the aorta arches over to the right side, the three branches have an arrangement the reverse of what is usual, the innominate supplying the left side, and the carotid and subclavian (which arise separately) the right side. In other cases, where the aorta takes its usual course, the two carotids may be joined in a common trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.¹

In some instances other arteries are found to arise from the arch of the aorta. Of these the most common are the bronchial, one or both, and the thyroidea ima; but the internal mammary and the inferior thyroid have been seen to arise from this vessel.

INNOMINATE ARTERY.

The innominate artery (brachio-cephalic) is the largest branch given off from the arch of the aorta. It arises, on a level with the upper border of the second right costal cartilage, from the commencement of the arch of the aorta in front of the left carotid, and, ascending obliquely to the upper border of the right sterno-clavicular articulation, divides into the right common carotid and right subclavian arteries. This vessel varies from an inch and a half to two inches in length.

Relations.—*In front*, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the remains of the thymus gland, the left innominate and right inferior thyroid veins which cross its root, and sometimes the inferior cervical cardiac branch of the right pneumogastric. *Behind*, it lies upon the trachea, which it crosses obliquely. On the *right side* is the right innominate vein, right pneumogastric nerve, and the pleura; and on the *left side*,

¹ The anomalies of the aorta and its branches are minutely described by Krause in Henle's *Anatomy* (Brunswick, 1868), vol. iii., p. 203 *et seq.*

the remains of the thymus gland, the origin of the left carotid artery, the left inferior thyroid vein, and the trachea.

Branches.—The innominate usually gives off no branches, but occasionally a small branch, the *thyroidea ima*, is given off from this vessel. It also sometimes gives off a *thymic* or *bronchial branch*. The *Thyroidea ima* ascends in front of the trachea to the lower part of the thyroid body, which it supplies. It varies greatly in size, and appears to compensate for deficiency or absence of one of the other thyroid vessels. It occasionally is found to arise from the right common carotid or from the aorta, the subclavian, or internal mammary vessels.

Peculiarities in Point of Division.—When the bifurcation of the innominate artery varies from the point above mentioned, it sometimes ascends a considerable distance above the sternal end of the clavicle; less frequently it divides below it. In the former class of cases its length may exceed two inches, and in the latter be reduced to an inch or less. These are points of considerable interest for the surgeon to remember in connection with the operation of tying this vessel.

Position.—When the aorta arches over to the right side, the innominate is directed to the left side of the neck instead of the right.

Collateral Circulation.—Allan Burns demonstrated, on the dead subject, the possibility of the establishment of the collateral circulation after ligature of the innominate artery, by tying and dividing that artery, after which, he says, "Even coarse injection, impelled into the aorta, passing freely by the anastomosing branches into the arteries of the right arm, filling them and all the vessels of the head completely" (*Surgical Anatomy of the Head and Neck*, p. 62). The branches by which this circulation would be carried on are very numerous; thus, all the communications across the middle line between the branches of the carotid arteries of opposite sides would be available for the supply of blood to the right side of the head and neck; while the anastomosis between the superior intercostal of the subclavian and the first aortic intercostal (see *infra* on the collateral circulation after obliteration of the thoracic aorta) would bring the blood, by a free and direct course, into the right subclavian: the numerous connections, also, between the intercostal arteries and the branches of the axillary and internal mammary arteries would, doubtless, assist in the supply of blood to the right arm, while the deep epigastric, from the external iliac, would, by means of its anastomosis with the internal mammary, compensate for any deficiency in the vascularity of the wall of the chest.

Surgical Anatomy.—Although the operation of tying the innominate artery has been performed by several surgeons for aneurism of the right subclavian extending inward as far as the Scalenus, in only five instances, according to Mr. Jacobson, has the patient survived. Mott's patient, however, on whom the operation was first performed, lived nearly four weeks, and Graefe's more than two months. The chief danger of the operation appears to be the frequency of secondary hemorrhage; but in the present day, with the practice of aseptic surgery and our greater knowledge of the use of the ligature, more favorable results may be anticipated. Other causes of death after operation are pleurisy, pericarditis, and suppurative cellulitis. The main obstacles to the operation are, as the student will perceive from his dissection of this vessel, the deep situation of the artery behind and beneath the sternum, and the number of important structures which surround it in every part.

In order to apply a ligature to this vessel, the patient is to be placed upon his back, with the thorax slightly raised, the head bent a little backward, and the shoulder on the side of the aneurism strongly depressed, so as to draw out the artery from behind the sternum into the neck. An incision three or more inches long is then made along the anterior border of the Sterno-mastoid muscle, terminating at the sternal end of the clavicle. From this point a second incision is carried about the same length along the upper border of the clavicle. The skin is then dissected back, and the Platysma divided on a director: the sternal end of the Sterno-mastoid is now brought into view, and, a director being passed beneath it and close to its under surface, so as to avoid any small vessels, it is to be divided; in like manner the clavicular origin is to be divided

throughout the whole or greater part of its attachment. By pressing aside any loose cellular tissue or vessels that may now appear the Sterno-hyoid and Sterno-thyroid muscles will be exposed, and must be divided, a director being previously passed beneath them. The inferior thyroid veins may come into view, and must be carefully drawn, either upward or downward, by means of a blunt hook, or tied with double ligatures and divided. After tearing through a strong fibro-cellular lamina, the right carotid is brought into view, and, being traced downward, the arteria innominata is arrived at. The left innominate vein should now be depressed; the right innominate vein, the internal jugular vein, and the pneumogastric nerve drawn to the right side; and a curved aneurism needle may then be passed around the vessel, close to its surface, and in a direction from below upward and inward, care being taken to avoid the right pleural sac, the trachea, and cardiac nerves. The ligature should be applied to the artery as high as possible, in order to allow room between it and the aorta for the formation of the coagulum. The importance of avoiding the thyroid plexus of veins during the primary steps of the operation, and the pleural sac whilst including the vessel in the ligature, should be most carefully borne in mind. After the artery has been secured, the common carotid should be tied about half an inch above its origin, and also the thyroidea ima if the vessel is of any size. The several muscles are united by buried sutures.

ARTERIES OF THE HEAD AND NECK.

The artery which supplies the head and neck is the Common Carotid: it ascends in the neck and divides into two branches: the External Carotid, supplying the superficial parts of the head and face and the greater part of the neck; and the Internal Carotid, supplying to a great extent the parts within the cranial cavity.

The Common Carotid Arteries.

The common carotid arteries, although occupying a nearly similar position in the neck, differ in position, and, consequently, in their relation at their origin. The right carotid arises from the innominate artery, behind the right sterno-clavicular articulation; the left from the highest part of the arch of the aorta. The left carotid is, consequently, longer, and at its origin is contained within the thorax. The course and relations of that portion of the left carotid which intervenes between the arch of the aorta and the left sterno-clavicular articulation will first be described (see Fig. 280).

The left carotid within the thorax ascends obliquely outward from the arch of the aorta to the root of the neck. *In front*, it is separated from the first piece of the sternum by the Sterno-hyoid and Sterno-thyroid muscles, the left innominate vein, and the remains of the thymus gland; *behind*, it lies on the trachea, œsophagus, and thoracic duct. *Internally*, it is in relation with the innominate artery, inferior thyroid veins and remains of thymus gland; *externally*, with the left pneumogastric nerve, left pleura, and lung. The left subclavian artery is posterior and slightly external to it.

In the neck the two common carotids resemble each other so closely that one description will apply to both. Each vessel passes obliquely upward from behind the sterno-clavicular articulation to a level with the upper border of the thyroid cartilage, opposite the fourth cervical vertebra, where it divides into the external

FIG. 284.—Plan of the branches of the external carotid.

FIG. 283.—Surgical anatomy of the arteries of the neck, showing the carotid and subclavian arteries.

and internal carotid; these names being derived from the distribution of the arteries to the external parts of the head and face and to the internal parts of the cranium and orbit respectively.

At the lower part of the neck the two common carotid arteries are separated from each other by a small interval, which contains the trachea; but at the upper part, the thyroid body, the larynx and pharynx project forward between the two vessels, and give the appearance of their being placed farther back in this situation. The common carotid artery is contained in a sheath derived from the deep cervical fascia, which also encloses the internal jugular vein and pneumogastric nerve, the vein lying on the outer side of the artery, and the nerve between

the artery and vein, on a plane posterior to both. On opening the sheath these three structures are seen to be separated from one another, each being enclosed in a separate fibrous investment.

Relations.—At the lower part of the neck the common carotid artery is very deeply seated, being covered by the integument, superficial fascia, Platysma, and deep cervical fascia, the Sterno-mastoid, Sterno-hyoid, and Sterno-thyroid muscles, and by the Omo-hyoid, opposite the cricoid cartilage; but in the upper part of its course, near its termination, it is more superficial, being covered merely by the integument, the superficial fascia, Platysma, deep cervical fascia, and inner margin of the Sterno-mastoid, and, when the latter is drawn backward, it is seen to be contained in a triangular space, bounded behind by the Sterno-mastoid, above by the posterior belly of the Digastric, and below by the anterior belly of the Omo-hyoid. This part of the artery is crossed obliquely, from within outward, by the sterno-mastoid artery; it is crossed also by the superior and middle thyroid veins, which terminate in the internal jugular; and, descending on its sheath in front, is seen the descendens hypoglossi nerve, this filament being joined by one or two branches from the cervical nerves, which cross the vessel from without inward. Sometimes the descendens hypoglossi is contained within the sheath. The middle thyroid vein crosses the artery about its middle, and the anterior jugular vein below; the latter, however, is separated from the artery by the Sterno-hyoid and Sterno-thyroid muscles. *Behind*, the artery is separated from the transverse processes of the vertebræ by the Longus colli and Rectus capitis anticus major, the sympathetic nerve being interposed between it and the muscles. The recurrent laryngeal nerve and inferior thyroid artery cross behind the vessel at its lower part. *Internally*, it is in relation with the trachea and thyroid gland, the later overlapping it, the inferior thyroid artery and recurrent laryngeal nerve being interposed: higher up, with the larynx and pharynx. On its *outer side* are placed the internal jugular vein and pneumogastric nerve.

At the lower part of the neck the internal jugular vein on the right side diverges from the artery, but on the left side it approaches it, and often overlaps its lower part. This is an important fact to bear in mind during the performance of any operation on the lower part of the left common carotid artery.

Peculiarities as to Origin.—The *right common carotid* may arise above or below the upper border of the sterno-clavicular articulation. This variation occurs in one out of about eight cases and a half, and the origin is more frequently below than above; or the artery may arise as a separate branch from the arch of the aorta or in conjunction with the left carotid. The *left common carotid* varies more frequently in its origin than the right. In the majority of abnormal cases it arises with the innominate artery, or, if the innominate artery is absent, the two carotids arise usually by a single trunk. It rarely joins with the left subclavian, except in cases of transposition of the arch.

Peculiarities as to Point of Division.—The most important peculiarities of this vessel, in a surgical point of view, relate to its place of division in the neck. In the majority of abnormal cases this occurs higher than usual, the artery dividing into two branches opposite the hyoid bone, or even higher; more rarely it occurs below, opposite the middle of the larynx or the lower border of the cricoid cartilage; and one case is related by Morgagni where the common carotid, only an inch and a half in length, divided at the root of the neck. Very rarely the common carotid ascends in the neck without any subdivision, the internal carotid being wanting; and in a few cases the common carotid has been found to be absent, the external and internal carotids arising directly from the arch of the aorta. This peculiarity existed on both sides in some instances, on one side in others.

Occasional Branches.—The common carotid usually gives off no branch previous to its bifurcation; but it occasionally gives origin to the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or, more rarely, the vertebral artery.

Surface Marking.—The carotid arteries are covered throughout their entire extent by the Sterno-mastoid muscle, but their course does not correspond to the anterior border of the muscle, which passes in a somewhat curved direction from the mastoid process to the sterno-clavicular joint. The course of the artery is indicated more exactly by a line drawn from the sternal end of the clavicle below, to a point midway between the angle of the jaw and the mastoid process above. That portion of the line below the level of the upper border of the thyroid cartilage would represent the course of the vessel.

Surgical Anatomy.—The operation of tying the common carotid artery may be necessary in a case of wound of that vessel or its branches, in aneurism, or in a case of pulsating tumor of the orbit or skull. If the wound involves the trunk of the common carotid, it will be necessary to tie the artery above and below the wounded part. But in cases of aneurism, or where one of the branches of the common carotid is wounded in an inaccessible situation, it may be judged necessary to tie the trunk. In such cases the whole of the artery is accessible, and any part may be tied except close to either end. When the case is such as to allow of a choice being made, the lower part of the carotid should never be selected as the spot upon which to place a ligature, for not only is the artery in this situation placed very deeply in the neck, but it is covered by three layers of muscles, and, on the left side, the internal jugular vein, in the great majority of cases, passes obliquely in front of it. Neither should the upper end be selected, for here the superior thyroid vein and its tributaries would give rise to very considerable difficulty in the application of a ligature. The point most favorable for the operation is that part of the vessel which is at the level of the cricoid cartilage. It occasionally happens that the carotid artery bifurcates below its usual position: if the artery be exposed at its point of bifurcation, both divisions of the vessel should be tied near their origin, in preference to tying the trunk of the artery near its termination; and if, in consequence of the entire absence of the common carotid or from its early division, two arteries, the external and internal carotids, are met with, the ligature should be placed on that vessel which is found on compression to be connected with the disease.

In this operation the direction of the vessel and the inner margin of the Sterno-mastoid are the chief guides to its performance. The patient should be placed on his back with the head thrown back and turned slightly to the opposite side: an incision is to be made, three inches long, in the direction of the anterior border of the Sterno-mastoid, so that the centre corresponds to the level of the cricoid cartilage: after dividing the integument, superficial fascia, and Platysma, the deep fascia must be cut through on a director, so as to avoid wounding numerous small veins that are usually found beneath. The head may now be brought forward so as to relax the parts somewhat, and the margins of the wound held asunder by retractors. The descendens hypoglossi nerve may now be exposed, and must be avoided, and, the sheath of the vessel having been raised by forceps, is to be opened to a small extent over the artery at its inner side. The internal jugular vein may present itself alternately distended and relaxed; this should be compressed both above and below, and drawn outward, in order to facilitate the operation. The aneurism needle is passed from the outside, care being taken to keep the needle in close contact with the artery, and thus avoid the risk of injuring the internal jugular vein or including the vagus nerve. Before the ligature is tied it should be ascertained that nothing but the artery is included in it.

Ligature of the Common Carotid at the Lower Part of the Neck.—This operation is sometimes required in cases of aneurism of the upper part of the carotid, especially if the sac is of large size. It is best performed by dividing the sternal origin of the Sterno-mastoid muscle, but may be done in some cases, if the aneurism is not of very large size, by an incision along the anterior border of the Sterno-mastoid, extending down to the sterno-clavicular articulation, and by then retracting the muscle. The easiest and best plan, however, is to make an incision two or three inches long down the lower part of the anterior border of the Sterno-mastoid muscle to the sterno-clavicular joint, and a second incision, starting from the termination of the first, along the upper border of the clavicle for about two inches. This incision is made through the superficial and deep fascia, and the sternal origin of the muscle exposed. This is to be divided on a director, and turned up, with the superficial structures, as a triangular flap. Some loose connective tissue is to be divided or torn through, and the outer border of the Sterno-hyoid muscle exposed. In doing this care must be taken not to wound the anterior jugular vein, which crosses the muscle to reach the external jugular or subclavian vein. The Sterno-hyoid, and with it the Sterno-thyroid, are to be drawn inward by means of a retractor,

and the sheath of the vessel is exposed. This must be opened with great care on its inner or tracheal side, so as to avoid the internal jugular vein. This is especially necessary on the left side, where the artery is commonly overlapped by the vein. On the right side there is usually an interval between the artery and the vein, and not the same risk of wounding the latter.

The common carotid artery, being a long vessel without any branches, is particularly suitable for the performance of Brasdor's operation for the cure of an aneurism of the lower part of the vessel. Brasdor's procedure consists in ligaturing the artery on the distal side of the aneurism, and in the case of the common carotid there are no branches given off from the vessel between the aneurism and the site of the ligature; hence the flow of blood through the sac of the aneurism is diminished and cure takes place in the usual way, by the deposit of laminated fibrin.

Collateral Circulation.—After ligature of the common carotid the collateral circulation can be perfectly established, by the free communication which exists between the carotid arteries of opposite sides, both without and within the cranium, and by enlargement of the branches of the subclavian artery on the side corresponding to that on which the vessel has been tied—the chief communication outside the skull taking place between the superior and inferior thyroid arteries, and the profunda cervicis and arteria princeps cervicis of the occipital; the vertebral taking the place of the internal carotid within the cranium.

Sir A. Cooper had an opportunity of dissecting, thirteen years after the operation, the case in which he first successfully tied the common carotid (the second case in which he performed the operation).¹ The injection, however, does not seem to have been a successful one. It showed merely that the arteries at the base of the brain (circle of Willis) were much enlarged on the side of the tied artery, and that the anastomosis between the branches of the external carotid on the affected side and those of the same artery on the sound side was free, so that the external carotid was pervious throughout.

The External Carotid Artery.

The **external carotid artery** (Fig. 283) commences opposite the upper border of the thyroid cartilage, and, taking a slightly curved course, passes upward and forward, and then inclines backward to the space between the neck of the condyle of the lower jaw and the external meatus, where it divides into the temporal and internal maxillary arteries. It rapidly diminishes in size in its course up the neck, owing to the number and large size of the branches given off from it. In the child it is somewhat smaller than the internal carotid, but in the adult the two vessels are of nearly equal size. At its commencement this artery is more superficial, and placed nearer the middle line than the internal carotid, and is contained in the triangular space bounded by the Sterno-mastoid behind, the Omo-hyoid below, and the posterior belly of the Digastric and Stylo-hyoid above.

Relations.—It is covered by the skin, superficial fascia, Platysma, deep fascia, and anterior margin of the Sterno-mastoid, crossed by the hypoglossal nerve, and by the lingual and facial veins; it is afterward crossed by the Digastric and Stylo-hyoid muscles, and higher up passes deeply into the substance of the parotid gland, where it lies beneath the facial nerve and the junction of the temporal and internal maxillary veins. *Internally* is the hyoid bone, wall of the pharynx, the superior laryngeal nerve, and the ramus of the jaw, from which it is separated by a portion of the parotid gland. *Externally*, in the lower part of its course, is the internal carotid artery. *Behind* it, near its origin, is the superior laryngeal nerve; and higher up, it is separated from the internal carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and part of the parotid gland.

Surface Marking.—The position of the external carotid artery may be marked out with sufficient accuracy by a line drawn from the front of the meatus of the external ear to the side of the cricoid cartilage, slightly arching the line forward.

Surgical Anatomy.—The application of a ligature to the external carotid may be required in case of wounds of this vessel, or of its branches when these cannot be tied, and in some cases of pulsating tumor of the scalp or face. The operation has not received the attention which it deserves, owing to the fear which surgeons have entertained of secondary hæmorrhage, on account of the number of branches given off from the vessel. This fear, however, has been shown by Mr. Cripps not to be well founded.¹ To tie this vessel near its origin, below the point where it is crossed by the Digastric, an incision about three inches in length should be made along the margin of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The ligature should be applied between the lingual and superior thyroid branches. To tie the vessel above the Digastric, between it and the parotid gland, an incision should be made, from the lobe of the ear to the great cornu of the os hyoides, dividing successively the skin, Platysma, and fascia. By drawing the Sterno-mastoid outward, and the posterior belly of the Digastric and Stylo-hyoid muscles downward, and separating them from the parotid gland, the vessel will be exposed, and a ligature may be applied to it. The circulation is at once re-established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid, and of the occipital with the branches of the subclavian, etc.

Branches.—The external carotid artery gives off eight branches, which, for convenience of description, may be divided into four sets. (See Fig. 284, Plan of the Branches).

<i>Anterior.</i>	<i>Posterior.</i>	<i>Ascending.</i>	<i>Terminal.</i>
Superior Thyroid.	Occipital.	Ascending Pha-	Superficial Temporal.
Lingual.	Posterior Auricular.	ryngeal.	Internal Maxillary.
Facial.			

The student is here reminded that many variations are met with in the number, origin, and course of these branches in different subjects; but the above arrangement is that which is found in the great majority of cases.

The **Superior Thyroid Artery** (Figs. 283 and 288) is the first branch given off from the external carotid, being derived from that vessel just below the great cornu of the hyoid bone. At its commencement it is quite superficial, being covered by the integument, fascia, and Platysma, and is contained in the triangular space bounded by the Sterno-mastoid, Digastric, and Omo-hyoid muscles. After running upward and inward for a short distance, it curves downward and forward, in an arched and tortuous manner, to the upper part of the thyroid gland, passing beneath the Omo-hyoid, Sterno-hyoid, and Sterno-thyroid muscles, and supplying them. It distributes numerous branches to the upper part of the gland, anastomosing with its fellow of the opposite side and with the inferior thyroid arteries. The branches supplying the gland are generally three in number: one, the largest, supplies principally the anterior surface of the gland; it courses along the inner border of the lobe as far as the upper border of the isthmus, and then passes in the substance of the isthmus to the middle line of the neck, where it anastomoses with the corresponding artery of the opposite side: a second branch courses along the external border of the lobe, and supplies this portion of the gland, and the third passes to the posterior surface, the upper part of which it supplies.

¹ *Med.-Chir. Trans.*, lxi., 229.

Besides the arteries distributed to the muscles by which it is covered and to the substance of the gland, the branches of the superior thyroid are the following:

Hyoid.	Superior laryngeal.
Superficial descending branch (Sterno-mastoid).	Crico-thyroid.

The **hyoid (infra-hyoid)** is a small branch which runs along the lower border of the os hyoides beneath the Thyro-hyoid muscle; after supplying the muscles connected to that bone, it forms an arch, by anastomosing with the vessel of the opposite side.

The **superficial descending or Sterno-mastoid branch** runs downward and outward across the sheath of the common carotid artery, and supplies the Sterno-mastoid and neighboring muscles and integument. There is frequently a separate branch from the external carotid distributed to the Sterno-mastoid muscle.

The **superior laryngeal**, larger than either of the preceding, accompanies the internal laryngeal nerve, beneath the Thyro-hyoid muscle: it pierces the thyro-hyoid membrane, and supplies the muscles, mucous membrane, and glands of the larynx, anastomosing with the branch from the opposite side.

The **crico-thyroid** is a small branch which runs transversely across the crico-thyroid membrane, communicating with the artery of the opposite side.

Surgical Anatomy.—The superior thyroid, or one of its branches, is often divided in cases of cut throat, giving rise to considerable hemorrhage. In such cases the artery should be secured, the wound being enlarged for that purpose, if necessary. The operation may be easily performed, the position of the artery being very superficial, and the only structures of importance covering it being a few small veins. The operation of tying the superior thyroid artery in bronchocele has been performed in numerous instances with partial or temporary success. When, however, the collateral circulation between this vessel and the artery of the opposite side, and the inferior thyroid, is completely re-established, the tumor usually regains its former size, and hence the operation has been given up, especially as better results are obtained by other means. Both thyroid arteries on the same side, and indeed all the four thyroid arteries, have been tied in enlarged thyroid.

The position of the superficial descending branch is of importance in connection with the operation of ligation of the common carotid artery. It crosses and lies on the sheath of this vessel, and may chance to be wounded in opening the sheath. The position of the crico-thyroid branch should be remembered, as it may prove the source of troublesome hemorrhage during the operation of laryngotomy.

The **Lingual Artery** (Fig. 288) arises from the external carotid between the superior thyroid and facial; it first runs obliquely upward and inward to the great cornu of the hyoid bone; it then curves downward and forward, forming a loop which is crossed by the hypoglossal nerve, and, passing beneath the Digastric and Stylo-hyoid muscles, it runs horizontally forward, beneath the Hyo-glossus, and finally, ascending almost perpendicularly to the tongue, turns forward on its under surface as far as the tip, under the name of the *ranine artery*.

Relations.—Its first, or oblique, portion is superficial, being contained in the same triangular space as the superior thyroid artery, resting upon the middle constrictor of the pharynx, and covered by the Platysma and fascia of the neck. Its second, or curved, portion also lies upon the middle constrictor, being covered at first by the tendon of the Digastric and the Stylo-hyoid muscle, and afterward by the Hyo-glossus, the latter muscle separating it from the hypoglossal nerve. Its third, or horizontal, portion lies between the Hyo-glossus and Genio-hyo-glossus muscles. The fourth, or terminal, part, under the name of the *ranine*, runs along the under surface of the tongue to its tip: it is very superficial, being covered only by the mucous membrane, and rests on the Lingualis on the outer side of the Genio-hyo-glossus. The hypoglossal nerve crosses the lingual artery, and then becomes separated from it, in the second part of its course, by the Hyo-glossus muscle.

The branches of the lingual artery are—the

Hyoid.	Sublingual.
Dorsalis Linguae.	Ranine.

The **hyoid branch** (*supra-hyoid*) runs along the upper border of the hyoid bone, supplying the muscles attached to it and anastomosing with its fellow of the opposite side.

The **dorsalis linguæ** (Fig. 288) arises from the lingual artery beneath the Hyoglossus muscle (which, in the figure, has been partly cut away, to show the vessel); it ascends to the dorsum of the tongue, and supplies the mucous membrane, the tonsil, soft palate, and epiglottis, anastomosing with its fellow from the opposite side. This artery is frequently represented by two or three small branches.

The **sublingual**, which may be described as a branch of bifurcation of the lingual artery, arises at the anterior margin of the Hyoglossus muscle, and runs forward between the Genio-hyo-glossus and the sublingual gland. It supplies the substance of the gland, giving branches to the Mylo-hyoid and neighboring muscles, the mucous membrane of the mouth and gums. One branch runs behind the alveolar process of the lower jaw in the substance of the gum to anastomose with a similar artery from the other side.

The **ranine** may be regarded as the other branch of bifurcation, or, as is more usual, as the continuation of the lingual artery; it runs along the under surface of the tongue, resting on the Inferior lingualis, and covered by the mucous membrane of the mouth; it lies on the outer side of the Genio-hyo-glossus, accompanied by the lingual nerve. On arriving at the tip of the tongue it has been said to anastomose with the artery of the opposite side, but this is denied by Hyrtl. These vessels in the mouth are placed one on each side of the frænum.

Surgical Anatomy.—The lingual artery may be divided near its origin in cases of cut throat, a complication that not unfrequently happens in this class of wounds; or severe hæmorrhage which cannot be restrained by ordinary means may ensue from a wound or deep ulcer of the tongue. In the former case the primary wound may be enlarged if necessary, and the bleeding vessels secured. In the latter case it has been suggested that the lingual artery should be tied near its origin. Ligation of the lingual artery is also occasionally practised, as a palliative measure, in cases of cancer of the tongue, in order to check the progress of the disease by starving the growth, and it is sometimes tied as a preliminary measure to removal of the tongue. The operation is a difficult one, on account of the depth of the artery, the number of important parts by which it is surrounded, the loose and yielding nature of the parts upon which it is supported, and its occasional irregularity of origin. An incision is to be made in a curved direction from a finger's breadth external to the symphysis of the jaw downward to the cornu of the hyoid bone, and then upward to near the angle of the jaw. Care must be taken not to carry this incision too far backward, for fear of endangering the facial vein. In the first incision the skin, superficial fascia, and Platysma will be divided, and the deep fascia exposed. This is then to be incised and the submaxillary gland exposed and pulled upward by retractors. A triangular space is now exposed, bounded internally by the posterior border of the Mylo-hyoid muscle: below and externally, by the tendon of the Digastric; and above, by the hypoglossal nerve. The floor of the space is formed by the Hyoglossus muscle, beneath which the artery lies. The fibres of this muscle are now to be cut through horizontally and the vessel exposed, care being taken, while near the vessel, not to open the pharynx.

Troublesome hæmorrhage may occur in the division of the frænum in children if the ranine artery, which lies on each side of it, is wounded. The student should remember that the operation is always to be performed with a pair of blunt-pointed scissors, and the mucous membrane only is to be divided by a very superficial cut, which cannot endanger any vessel. The scissors, also, should be directed away from the tongue. Any further liberation of the tongue which may be necessary can be effected by tearing.

The **Facial Artery** (Fig. 285) arises a little above the lingual, and passes obliquely upward, beneath the Digastric and Stylo-hyoid muscles, and frequently beneath the hypoglossal nerve; it now runs forward under cover of the body of the lower jaw, lodged in a groove on the posterior surface of the submaxillary gland; this may be called the cervical part of the artery. It then curves upward over the body of the jaw at the anterior inferior angle of the Masseter muscle; passes forward and upward across the cheek to the angle of the mouth, then upward along the side of the nose, and terminates at the inner canthus of the eye, under the name of the *angular artery*. This vessel, both in the neck and on the face, is remarkably tortuous: in the former situation, to accommodate itself to the movements of the pharynx in deglutition, and in the latter to the movements of the jaw and the lips and cheeks.

Cervical Branches.

Inferior or Ascending Palatine.
 Tonsillar.
 Submaxillary.
 Submental.
 Muscular.

Facial Branches.

Muscular.
 Inferior Labial.
 Inferior Coronary.
 Superior Coronary.
 Lateral Nasal.
 Angular.

The **inferior or ascending palatine** (Fig. 289) passes up between the Stylo-glossus and Stylo-pharyngeus to the outer side of the pharynx, along which it is continued between the Superior constrictor and the Internal pterygoid to near the base of the skull. It supplies the neighboring muscles, the tonsil, and Eustachian tube, and divides, near the Levator palati, into two branches: one follows the course of the Levator palati, and, winding over the upper border of the Superior constrictor, supplies the soft palate and the palatine glands, anastomosing with its fellow of the opposite side and with the posterior palatine branch of the internal maxillary artery; the other pierces the Superior constrictor and supplies the tonsil, anastomosing with the tonsillar and ascending pharyngeal arteries.

The **tonsillar branch** (Fig. 289) passes up between the Internal pterygoid and Stylo-glossus, and then ascends along the side of the pharynx, perforating the Superior constrictor, to ramify in the substance of the tonsil and root of the tongue.

The **submaxillary or glandular branches** consist of three or four large vessels, which supply the submaxillary gland, some being prolonged to the neighboring muscles, lymphatic glands, and integument.

The **submental**, the largest of the cervical branches, is given off from the facial artery just as that vessel quits the submaxillary gland: it runs forward upon the Mylo-hyoid muscle, just below the body of the jaw and beneath the Digastric; after supplying the surrounding muscles, and anastomosing with the sublingual artery by branches which perforate the Mylo-hyoid muscle, it arrives at the symphysis of the chin, where it turns over the border of the jaw and divides into a superficial and a deep branch; the former passes between the integument and Depressor labii inferioris, supplies both, and anastomoses with the inferior labial. The deep branch passes between the latter muscle and the bone, supplies the lip, and anastomoses with the inferior labial and mental arteries.

The **muscular branches** are distributed to the Internal pterygoid and Stylo-hyoid in the neck, and to the Masseter and Buccinator on the face.

The **inferior labial** passes beneath the Depressor anguli oris, to supply the muscles and integument of the lower lip, anastomosing with the inferior coronary and submental branches of the facial, and with the mental branch of the inferior dental artery.

The **inferior coronary** is derived from the facial artery, near the angle of the mouth: it passes upward and inward beneath the depressor anguli oris, and, penetrating the Orbicularis oris muscle, runs in a tortuous course along the edge of the lower lip between this muscle and the mucous membrane, inosculating with the artery of the opposite side. This artery supplies the labial glands, the mucous membrane, and muscles of the lower lip, and anastomoses with the inferior labial and the mental branch of the inferior dental artery.

The **superior coronary** is larger and more tortuous in its course than the preceding. It follows the same course along the edge of the upper lip, lying between the mucous membrane and the Orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the textures of the upper lip, and gives off in its course two or three vessels which ascend to the nose. One, named the *inferior artery of the septum*, ramifies on the septum of the nares as far as the point of the nose; another, the *artery of the ala*, supplies the ala of the nose.

The **lateralis nasi** is derived from the facial, as that vessel is ascending along the side of the nose; it supplies the ala and dorsum of the nose, anastomosing

with its fellow, the nasal branch of the ophthalmic, the inferior artery of the septum, the artery of the ala, and the infra-orbital.

The **angular artery** is the termination of the trunk of the facial; it ascends to the inner angle of the orbit, imbedded in the fibres of the Levator labii superioris alæque nasi, and accompanied by a large vein, the *angular*; it distributes some branches on the cheek which anastomose with the infra-orbital, and after supplying the lachrymal sac and Orbicularis palpebrarum muscle, terminates by anastomosing with the nasal branch of the ophthalmic artery.

FIG. 286.—The occipital artery and its relations. (From a dissection by Mr. Gerald S. Hughes.)

The anastomoses of the facial artery are very numerous, not only with the vessel of the opposite side, but, in the neck, with the sublingual branch of the lingual; with the ascending pharyngeal; with the posterior palatine, a branch of the internal maxillary, by its inferior or ascending palatine and tonsillar branches; on the face, with the mental branch of the inferior dental as it emerges from the mental

foramen, with the transverse facial, a branch of the temporal; with the infra-orbital, a branch of the internal maxillary, and with the nasal branch of the ophthalmic.

Peculiarities.—The facial artery not unfrequently arises by a common trunk with the lingual. This vessel is also subject to some variations in its size and in the extent to which it supplies the face. It occasionally terminates as the submental, and not unfrequently supplies the face only as high as the angle of the mouth or nose. The deficiency is then supplied by enlargement of one of the neighboring arteries.

Surgical Anatomy.—The passage of the facial artery over the body of the jaw would appear to afford a favorable position for the application of pressure in case of hæmorrhage from the lips, the result either of an accidental wound or during an operation; but its application is useless, except for a very short time, on account of the free communication of this vessel with its fellow and with numerous branches from different sources. In a wound involving the lip it is better to seize the part between the fingers, and evert it, when the bleeding vessel may be at once secured with pressure-forceps. In order to prevent hæmorrhage in cases of removal of diseased growths from the part, the lip should be compressed on each side between the fingers and thumb or by a pair of specially devised clamp-forceps, whilst the surgeon excises the diseased part. In order to stop hæmorrhage where the lip has been divided in an operation, it is necessary, in uniting the edges of the wound, to pass the sutures through the cut edges, almost as deep as its mucous surface; by these means not only are the cut surfaces more neatly and securely adapted to each other, but the possibility of hæmorrhage is prevented by including in the suture the divided artery. If the suture is, on the contrary, passed through merely the cutaneous portion of the wound, hæmorrhage occurs into the cavity of the mouth. The student should, lastly, observe the relation of the angular artery to the lachrymal sac, and it will be seen that, as the vessel passes up along the inner margin of the orbit, it ascends on its nasal side. In operating for fistula lachrymalis the sac should always be opened on its outer side, in order that this vessel may be avoided.

The **Occipital Artery** (Figs. 285, 286) arises from the posterior part of the external carotid, opposite the facial, near the lower margin of the Digastric muscle. At its origin it is covered by the posterior belly of the Digastric and Stylo-hyoid muscles, and the hypoglossal nerve winds around it from behind forward; higher up, it passes across the internal carotid artery, the internal jugular vein, and the pneumogastric and spinal accessory nerves; it then ascends to the interval between the transverse process of the atlas and the mastoid process of the temporal bone, and passes horizontally backward, grooving the surface of the latter bone, being covered by the Sterno-mastoid, Splenius, Trachelo-mastoid, and Digastric muscles, and resting upon the Rectus lateralis, the Superior oblique, and Complexus muscles; it then changes its course and passes vertically upward, pierces the fascia which connects the cranial attachment of the Trapezius with the Sterno-mastoid, and ascends in a tortuous course over the occiput, as high as the vertex, where it divides into numerous branches. It is accompanied in the latter part of its course by the great occipital, and occasionally by a cutaneous filament from the suboccipital nerve.

The branches given off from this vessel are—

Muscular.	Auricular.
Sterno-mastoid.	Meningeal.
Arteria Princeps Cervicis.	

The **muscular branches** supply the Digastric, Stylo-hyoid, Splenius, and Trachelo-mastoid muscles.

The **sterno-mastoid** is a large and constant branch, generally arising from the artery close to its commencement, but sometimes springing directly from the external carotid. It first passes downward and backward over the hypoglossal nerve, and enters the substance of the muscle in company with the spinal accessory nerve.

The **auricular branch** supplies the back part of the concha. It frequently gives off a branch, which enters the skull through the mastoid foramen and supplies the dura mater, the diploë, and the mastoid cells.

The **meningeal branch** ascends with the internal jugular vein, and enters the skull through the foramen lacerum posterius, to supply the dura mater in the posterior fossa.

The **arteria princeps cervicis** (Fig. 289), the largest branch of the occipital, descends along the back part of the neck and divides into a superficial and a deep

portion. The former runs beneath the Splenius, giving off branches which perforate that muscle to supply the Trapezius, which anastomose with the superficial cervical artery, a branch of the transversalis colli: the latter passes beneath the Complexus between it and the Semispinalis colli, and anastomoses with branches from the vertebral and with the deep cervical artery, a branch of the superior intercostal. The anastomosis between these vessels serves mainly to establish the collateral circulation after ligation of the carotid or subclavian artery.

The cranial branches of the occipital artery are distributed upon the occiput; they are very tortuous, and lie between the integument and Occipito-frontalis, anastomosing with the artery of the opposite side, the posterior auricular and temporal arteries. They supply the back part of the Occipito-frontalis muscle, the integument, and pericranium.

The **Posterior Auricular Artery** (Fig. 285) is a small vessel which arises from the external carotid, above the Digastric and Stylo-hyoid muscles, opposite the apex of the styloid process. It ascends, under cover of the parotid gland, on the styloid process of the temporal bone, to the groove between the cartilage of the ear and the mastoid process, immediately above which it divides into its two terminal branches, the auricular and mastoid. Just before arriving at the mastoid process, this artery is crossed by the portio dura, and has beneath it the spinal accessory nerve.

Besides several small branches to the Digastric, Stylo-hyoid, and Sterno-mastoid muscles and to the parotid gland, this vessel gives off three branches:

Stylo-mastoid.

Auricular.

Mastoid.

The **stylo-mastoid branch** enters the stylo-mastoid foramen, and supplies the tympanum, mastoid cells, and semicircular canals. In the young subject a branch from this vessel forms, with the tympanic branch from the internal maxillary, a vascular circle, which surrounds the membrana tympani, and from which delicate vessels ramify on that membrane. It anastomoses with the petrosal branch of the middle meningeal artery by a twig which enters the hiatus Fallopii.

The **auricular branch**, one of the terminal branches, ascends behind the ear, beneath the Retrahens auriculam muscle, and is distributed to the back part of the cartilage of the ear, upon which it ramifies minutely, some branches curving round the margin of the fibro-cartilage, others perforating it, to supply its anterior surface. It anastomoses with the posterior branch of the superficial temporal and also with its anterior auricular branches.

The **mastoid branch** passes backward, over the Sterno-mastoid muscle, to the scalp above and behind the ear. It supplies the posterior belly of the Occipito-frontalis muscle and the scalp in this situation. It anastomoses with the occipital artery.

The **Ascending Pharyngeal Artery** (Fig. 289), the smallest branch of the external carotid, is a long, slender vessel, deeply seated in the neck, beneath the other branches of the external carotid and the Stylo-pharyngeus muscle. It arises from the back part of the external carotid, near the commencement of that vessel, and ascends vertically between the internal carotid and the side of the pharynx, to the under surface of the base of the skull, lying on the Rectus capitis anticus major. Its branches may be subdivided into four sets:

Prevertebral.

Pharyngeal.

Tympanic.

Meningeal.

The **prevertebral branches** are numerous small vessels which supply the Recti capitis antici and Longus colli muscles, the sympathetic, hypoglossal, and pneumogastric nerves, and the lymphatic glands, anastomosing with the ascending cervical artery.

The **pharyngeal branches** are three or four in number. Two of these descend to supply the middle and inferior Constrictors and the Stylo-pharyngeus, ramifying in their substance and in the mucous membrane lining them. The largest of the pharyngeal branches passes inward, running upon the Superior constrictor, and sends ramifications to the soft palate and tonsil, which take the place of the

ascending palatine branch of the facial artery when that vessel is of small size. A twig from this branch supplies the Eustachian tube.

The **tympanic branch** is a small artery which passes through a minute foramen in the petrous portion of the temporal bone, in company with the tympanic branch of the Glosso-pharyngeal nerve to supply the inner wall of the tympanum and anastomose with the other tympanic arteries.

The **meningeal branches** consist of several small vessels, which pass through foramina in the base of the skull, to supply the dura mater. One, the posterior meningeal, enters the cranium through the foramen lacerum posterius; a second passes through the foramen lacerum medium; and occasionally a third through the anterior condyloid foramen. They are all distributed to the dura mater.

Surgical Anatomy.—The ascending pharyngeal artery has been wounded from the throat, as in the case in which the stem of a tobacco-pipe was driven into the vessel, causing fatal hemorrhage.

The **Superficial Temporal Artery** (Fig. 285), the smaller of the two terminal branches of the external carotid, appears, from its direction, to be the continuation of that vessel. It commences in the substance of the parotid gland, in the interspace between the neck of the lower jaw and the external auditory meatus, crosses over the posterior root of the zygoma, passes beneath the *Attrahens auriculam* muscle, lying on the temporal fascia, and divides, about two inches above the zygomatic arch, into two branches, an anterior and a posterior.

The **anterior temporal** runs tortuously upward and forward to the forehead, supplying the muscles, integument, and pericranium in this region, and anastomoses with the supra-orbital and frontal arteries.

The **posterior temporal**, larger than the anterior, curves upward and backward along the side of the head, lying superficial to the temporal fascia, and inosculates with its fellow of the opposite side, and with the posterior auricular and occipital arteries.

The superficial temporal artery, as it crosses the zygoma, is covered by the *Attrahens auriculam* muscle, and by a dense fascia given off from the parotid gland: it is crossed by the temporo-facial division of the facial nerve and one or two veins, and is accompanied by the auriculo-temporal nerve, which lies behind it. Besides some twigs to the parotid gland, the articulation of the jaw, and the Masseter muscle, its branches are, the

Transverse Facial.

Middle Temporal.

Anterior Auricular.

The **transverse facial** is given off from the temporal before that vessel quits the parotid gland; running forward through its substance, it passes transversely across the face, between Stenson's duct and the lower border of the zygoma, and divides on the side of the face into numerous branches, which supply the parotid gland, the Masseter muscle, and the integument, anastomosing with the facial, masseteric, and infra-orbital arteries. This vessel rests on the Masseter, and is accompanied by one or two branches of the facial nerve. It is sometimes a branch of the external carotid.

The **middle temporal** artery arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the Temporal muscle, anastomosing with the deep temporal branches of the internal maxillary. It occasionally gives off an orbital branch, which runs along the upper border of the zygoma, between the two layers of the temporal fascia, to the outer angle of the orbit. This branch, which may arise directly from the superficial temporal artery, supplies the *Orbicularis palpebrarum*, and anastomoses with the lachrymal and palpebral branches of the ophthalmic artery.

The **anterior auricular branches** are distributed to the anterior portion of the pinna, the lobule, and part of the external meatus, anastomosing with branches of the posterior auricular.

Surgical Anatomy.—Formerly the operation of arteriotomy was performed upon this vessel in cases of inflammation of the eye or brain, but now the operation is probably never performed. If the student will consider the relations of the trunk of the vessel as it crosses the zygomatic arch, with the surrounding structures, he will observe that it is covered by a thick and dense fascia, crossed by one of the main divisions of the facial nerve and one or two veins, and accompanied by the auriculo-temporal nerve. Bleeding should not be performed in this situation, as much difficulty may arise from the dense fascia over the vessel preventing a free flow of blood, and considerable pressure is requisite afterward to arrest the hemorrhage. Again, a varicose aneurism may be formed by the accidental opening of one of the veins in front of the artery; or severe neuralgic pain may arise from the operation implicating one of the nervous filaments in the neighborhood. The anterior branch, on the contrary, is subcutaneous, is a large vessel, and is readily compressed; it is consequently more suitable for the operation.

The **Internal Maxillary** (Fig. 287), the larger of the two terminal branches of the external carotid, arises from that vessel opposite the neck of the condyle of the lower jaw, and is at first embedded in the substance of the parotid gland; it passes inward between the ramus of the jaw and the internal lateral ligament, and then upon the outer surface of the External pterygoid muscle to the speno-maxillary fossa, to supply the deep structures of the face. For convenience of description it is divided into three portions: a maxillary, a pterygoid, and a speno-maxillary.

In the first part of its course (*maxillary portion*) the artery passes horizontally forward and inward, between the ramus of the jaw and the internal lateral ligament. The artery here lies parallel to and a little below the auriculo-temporal nerve; it crosses the inferior dental nerve, and lies along the lower border of the External pterygoid muscle.

In the second part of its course (*pterygoid portion*) it runs obliquely forward, and upward upon the outer surface of the External pterygoid muscle, being covered by the ramus of the lower jaw and lower part of the Temporal muscle; or it may pass on the inner surface of the External pterygoid muscle to reach the interval between its two heads, between which it passes to reach the speno-maxillary fossa.

In the third part of its course (*spheno-maxillary portion*) it approaches the superior maxillary bone, and enters the speno-maxillary fossa in the interval between the two heads of the External pterygoid, where it lies in relation with Meckel's ganglion, and gives off its terminal branches.

The branches of this vessel may be divided into three groups, corresponding with its three divisions.

BRANCHES OF THE FIRST OR MAXILLARY PORTION (Fig. 288).

Tympanic (anterior).

Deep auricular.

Middle meningeal.

Small meningeal.

Inferior dental.

The **tympanic branch** passes upward behind the articulation of the lower jaw, enters the tympanum through the Glaserian fissure, and ramifies upon the membrana tympani, forming a vascular circle around the membrane with the stylo-mastoid artery, and anastomosing with the Vidian and the tympanic branch from the internal carotid.

The **deep auricular branch** often arises in common with the preceding. It passes upward in the substance of the parotid gland, behind the temporo-maxillary articulation, pierces the cartilaginous or bony wall of the external auditory meatus, and supplies its cuticular lining and the outer surface of the membrana tympani.

The **middle meningeal** is the largest of the branches which supply the dura mater. It arises from the internal maxillary, between the internal lateral ligament and the neck of the jaw, and passes vertically upward between the two roots of the auriculo-temporal nerve to the foramen spinosum of the sphenoid bone. On entering the cranium it divides into two branches, anterior and posterior. The *anterior branch*, the larger, crosses the great ala of the sphenoid, and

reaches the groove, or canal, in the anterior inferior angle of the parietal bone: it then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upward over the parietal bone as far as the vertex, and others backward to the occipital bone. The *posterior branch* crosses the squamous portion of the temporal, and on the inner surface of the parietal

FIG. 287.—The internal maxillary artery and its branches.

FIG. 288.—Plan of the branches.

bone divides into branches which supply the posterior part of the dura mater and cranium. The branches of this vessel are distributed partly to the dura mater, but chiefly to the bones; they anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal.

The middle meningeal on entering the cranium gives off the following collateral branches: 1. Numerous small vessels to the Gasserian ganglion, and to the dura mater in this situation. 2. A branch (*petrosal branch*), which enters the hiatus Fallopii, supplies the facial nerve, and anastomoses with the stylo-mastoid branch of the posterior auricular artery. 3. A minute *tympanic* branch, which runs in the canal for the Tensor tympani muscle, and supplies this muscle and the lining membrane of the canal. 4. Orbital branches, which pass through the sphenoidal fissure, or through separate canals in the great wing of the sphenoid to anastomose with the lachrymal or other branches of the ophthalmic artery. 5. Temporal or anastomotic branches, which pass through foramina in the great wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries.

Surgical Anatomy.—The middle meningeal is an artery of considerable surgical importance, as it may be injured in fractures of the temporal region of the skull, and the injury may be followed by considerable hæmorrhage between the bone and dura mater, which may cause compression of the brain and require the operation of trephining for its relief. This artery crosses the anterior inferior angle of the parietal bone at a point $1\frac{1}{2}$ inches behind the external angular process of the frontal bone, and $1\frac{1}{4}$ inches above the zygoma. From this point the anterior branch passes upward and slightly backward to the sagittal suture, lying about $\frac{1}{2}$ inch to $\frac{3}{4}$ inch behind the coronal suture. The posterior branch passes upward and backward over the squamous portion of the temporal bone. In order to expose the artery as it lies in the canal in the parietal bone, a semilunar incision, with its convexity upward, should be made, commencing an inch behind the external angular process, and carried backward for 2 inches. The structures cut through are: (1) skin; (2) superficial fascia, with branches of the superficial temporal vessels and nerves; (3) the fascia continued down from the aponeurosis of the Occipito-frontalis; (4) the two layers of the temporal fascia; (5) the temporal muscle; (6) the deep temporal vessels; (7) the pericranium; and (8) the bone.

The **small meningeal** is sometimes derived from the preceding. It enters the skull through the foramen ovale, and supplies the Gasserian ganglion and dura mater.

The **inferior dental** descends with the inferior dental nerve to the foramen on the inner side of the ramus of the jaw. It runs along the dental canal in the substance of the bone, accompanied by the nerve, and opposite the first bicuspid tooth divides into two branches, incisor and mental; the former is continued forward beneath the incisor teeth as far as the symphysis, where it anastomoses with the artery of the opposite side; the mental branch escapes with the nerve at the mental foramen, supplies the structures composing the chin, and anastomoses with the submental inferior labial and inferior coronary arteries. Near its origin the inferior dental artery gives off a *lingual* branch, which descends with the lingual (gustatory) nerve and supplies the mucous membrane of the mouth. As the inferior dental artery enters the foramen it gives off a *mylo-hyoid branch*, which runs in the mylo-hyoid groove, and ramifies on the under surface of the Mylo-hyoid muscle. The dental and incisor arteries during their course through the substance of the bone give off a few twigs which are lost in the cancellous tissue, and a series of branches which correspond in number to the roots of the teeth: these enter the minute apertures at the extremities of the fangs and supply the pulp of the teeth.

BRANCHES OF THE SECOND OR PTERYGOID PORTION.

Deep Temporal.
Pterygoid.

Masseteric.
Buccal.

These branches are distributed, as their names imply, to the muscles in the maxillary region.

The **deep temporal** branches, two in number, anterior and posterior, each occupy that part of the temporal fossa indicated by its name. Ascending between the Temporal muscle and pericranium, they supply that muscle and anastomose with the middle temporal artery, the anterior branch communicating with the lachrymal through small branches which perforate the malar bone and great wing of the sphenoid.

The **pterygoid** branches, irregular in their number and origin, supply the Pterygoid muscles.

The **masseteric** is a small branch which passes outward, above the sigmoid notch of the lower jaw, to the deep surface of the Masseter. It supplies that muscle, and anastomoses with the masseteric branches of the facial and with the transverse facial artery.

The **buccal** is a small branch which runs obliquely forward between the Internal pterygoid and the ramus of the jaw, to the outer surface of the Buccinator, to which it is distributed, anastomosing with branches of the facial artery.

BRANCHES OF THE THIRD OR SPHENO-MAXILLARY PORTION.

Alveolar.	Vidian.
Infra-orbital.	Pterygo-palatine.
Posterior or Descending Palatine.	Naso- or Spheno-palatine.

The **alveolar** or **posterior dental branch** is given off from the internal maxillary by a common branch with the infra-orbital, and just as the trunk of the vessel is passing into the spheno-maxillary fossa. Descending upon the tuberosity of the superior maxillary bone, it divides into numerous branches, some of which enter the posterior dental canals, to supply the molar and bicuspid teeth and the lining of the antrum, and others are continued forward on the alveolar process to supply the gums.

The **infra-orbital** appears, from its direction, to be the continuation of the trunk of the internal maxillary. It arises from that vessel by a common trunk with the preceding branch, and runs along the infra-orbital canal with the superior maxillary nerve, emerging upon the face at the infra-orbital foramen, beneath the Levator labii superioris. Whilst contained in the canal, it gives off branches which ascend into the orbit, and assist in supplying the Inferior rectus and Inferior oblique muscles and the lachrymal gland. Other branches (*anterior dental*) descend through the anterior dental canals in the bone, to supply the mucous membrane of the antrum and the front teeth of the upper jaw. On the face, some branches pass upward to the inner angle of the orbit and the lachrymal sac, anastomosing with the angular branch of the facial artery; other branches pass inward toward the nose, anastomosing with the nasal branch of the ophthalmic; and other branches descend beneath the Levator labii superioris, and anastomose with the transverse facial and buccal arteries.

The four remaining branches arise from that portion of the internal maxillary which is contained in the spheno-maxillary fossa.

The **descending palatine** descends through the posterior palatine canal with the anterior palatine branch of Meckel's ganglion, and, emerging from the posterior palatine foramen, runs forward in a groove on the inner side of the alveolar border of the hard palate to the anterior palatine canal, where the terminal branch of the artery passes upward through the foramen of Stenson to anastomose with the naso-palatine artery. Its branches are distributed to the gums, the mucous membrane of the hard palate, and the palatine glands. Whilst it is contained in the palatine canal it gives off branches which descend in the accessory palatine canals to supply the soft palate and tonsil, anastomosing with the ascending palatine artery.

Surgical Anatomy.—The position of the descending palatine artery on the hard palate should be borne in mind in performing an operation for the closure of a cleft in the hard palate, as it is in danger of being wounded, and may give rise to formidable hemorrhage. In one case in which it was wounded it was necessary to plug the posterior palatine canal in order to arrest the bleeding.

The **Vidian branch** passes backward along the Vidian canal with the Vidian nerve. It is distributed to the upper part of the pharynx and Eustachian tube, sending a small branch into the tympanum, which anastomoses with the other tympanic arteries.

The **pterygo-palatine** is a very small branch, which passes backward through the pterygo-palatine canal with the pharyngeal nerve, and is distributed to the upper part of the pharynx and Eustachian tube.

The **spheno-palatine** passes through the spheno-palatine foramen into the cavity of the nose, at the back part of the superior meatus, and divides into two branches: one internal, the *naso-palatine* or *artery of the septum*, passes obliquely downward and forward along the septum nasi, supplies the mucous membrane, and anastomoses in front with the terminal branch of the descending palatine. The external branches, two or three in number, supply the mucous membrane covering the lateral wall of the nose, the antrum, and the ethmoid and sphenoid cells.

SURGICAL ANATOMY OF THE TRIANGLES OF THE NECK.

The student having considered the relative anatomy of the large arteries of the neck and their branches, and the relations they bear to the veins and nerves, should now examine these structures collectively, as they present themselves in certain regions of the neck, in each of which important operations are constantly being performed.

The side of the neck presents a somewhat quadrilateral outline, limited, above, by the lower border of the body of the jaw, and an imaginary line extending from the angle of the jaw to the mastoid process; below, by the prominent upper border of the clavicle; in front, by the median line of the neck; behind, by the anterior margin of the Trapezius muscle. This space is subdivided into two large triangles by the Sterno-mastoid muscle, which passes obliquely across the neck, from the sternum and clavicle below to the mastoid process above. The triangular space in front of this muscle is called the *anterior triangle*; and that behind it, the *posterior triangle*.

ANTERIOR TRIANGLE OF THE NECK.

The *anterior triangle* is bounded, in front, by a line extending from the chin to the sternum; behind, by the anterior margin of the Sterno-mastoid; its base, directed upward, is formed by the lower border of the body of the jaw and a line extending from the angle of the jaw to the mastoid process; its apex is below, at the sternum. This space is subdivided into three smaller triangles by the Digastric muscle above and the anterior belly of the Omo-hyoid below. These smaller triangles are named, from below upward, the inferior carotid, the superior carotid, and the submaxillary triangle.

The *Inferior Carotid Triangle* is bounded, in front, by the median line of the neck; behind, by the anterior margin of the Sterno-mastoid; above, by the anterior belly of the Omo-hyoid; and is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are some of the descending branches of the superficial cervical plexus. Beneath these superficial structures are the Sterno-hyoid and Sterno-thyroid muscles, which, together with the anterior margin of the Sterno-mastoid, conceal the lower part of the common carotid artery.¹

This vessel is enclosed within its sheath, together with the internal jugular vein and pneumogastric nerve; the vein lying on the outer side of the artery on the right side of the neck, but overlapping it below on the left side; the nerve lying between the artery and vein, on a plane posterior to both. In front of the sheath are a few filaments descending from the loop of communication between the descendens and communicans hypoglossi; behind the sheath are seen the inferior thyroid artery, the recurrent laryngeal nerve, and the sympathetic nerve; and on its inner side, the trachea, the thyroid gland—much more prominent in the female than in the male—and the lower part of the larynx. By cutting into the upper part of this space and slightly displacing the Sterno-mastoid muscle the common carotid artery may be tied below the Omo-hyoid muscle.

The *Superior Carotid Triangle* is bounded, behind, by the Sterno-mastoid; below, by the anterior belly of the Omo-hyoid; and above, by the Posterior belly of the Digastric muscle. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and superficial cervical nerves. Its floor is formed by parts of the Thyro-hyoid, Hyo-glossus, and the inferior and middle Constrictor muscles of the pharynx. This space, when dissected, is seen to contain the upper part of the common carotid

¹ Therefore the common carotid artery and internal jugular vein are not, strictly speaking, contained in this triangle, since they are covered by the Sterno-mastoid muscle; that is to say, lie behind the anterior border of that muscle, which forms the posterior border of the triangle. But as they lie very close to the structures which are really contained in the triangle, and whose position it is essential to remember in operating on this part of the artery, it has seemed expedient to study the relations of all these parts together.

artery, which bifurcates opposite the upper border of the thyroid cartilage into the external and internal carotid. These vessels are occasionally somewhat concealed from view by the anterior margin of the Sterno-mastoid muscle, which overlaps them. The external and internal carotids lie side by side, the external being the more anterior of the two. The following branches of the external carotid are also met with in this space: the superior thyroid, running forward and downward; the lingual, directly forward; the facial, forward and upward; the occipital, backward; and the ascending pharyngeal directly upward on the inner side of the internal carotid. The veins met with are: the internal jugular, which lies on the outer side of the common and internal carotid arteries, and veins corresponding to the above-mentioned branches of the external carotid—viz., the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital, all of which accompany their corresponding arteries and terminate in the internal jugular. The nerves in this space are the following: In front of the sheath of the common carotid is the descendens hypoglossi. The hypoglossal nerve crosses both the internal and external carotids above, curving round the occipital artery at its origin. Within the sheath, between the artery and vein, and behind both, is the pneumogastric nerve; behind the sheath, the sympathetic. On the outer side of the vessels the spinal accessory nerve runs for a short distance before it pierces the Sterno-mastoid muscle; and on the inner side of the external carotid, just below the hyoid bone, may be seen the internal laryngeal nerve; and, still more inferiorly, the external laryngeal nerve. The upper part of the larynx and lower part of the pharynx are also found in the front part of this space.

The **Submaxillary Triangle** corresponds to the part of the neck immediately beneath the body of the jaw. It is bounded, above, by the lower border of the body of the jaw and a line drawn from its angle to the mastoid process; below, by the posterior belly of the Digastric and Stylo-hyoid muscles; in front, by the anterior belly of the Digastric. It is covered by the integument, superficial fascia, Platysma, and deep fascia, ramifying between which are branches of the facial and ascending filaments of the superficial cervical nerves. Its floor is formed by the Mylo-hyoid and Hyo-glossus muscles. This space contains, in front, the submaxillary gland, superficial to which is the facial vein, while imbedded in it are the facial artery and its glandular branches; beneath this gland, on the surface of the Mylo-hyoid muscle, are the submental artery and the mylo-hyoid artery and nerve. The posterior part of this triangle is separated from the anterior part by the stylo-maxillary ligament: it contains the external carotid artery, ascending deeply in the substance of the parotid gland: this vessel here lies in front of, and superficial to, the internal carotid, being crossed by the facial nerve, and gives off in its course the posterior auricular, temporal, and internal maxillary branches: more deeply are the internal carotid, the internal jugular vein, and the pneumogastric nerve, separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles and the glosso-pharyngeal nerve.¹

POSTERIOR TRIANGLE OF THE NECK.

The **posterior triangle** is bounded, in front, by the Sterno-mastoid muscle; behind, by the anterior margin of the Trapezius; its base corresponds to the middle third of the clavicle; its apex, to the occiput. The space is crossed, about an inch above the clavicle, by the posterior belly of the Omo-hyoid, which divides it unequally into two, an upper or occipital and a lower or subclavian triangle.

The **Occipital**, the larger division of the posterior triangle, is bounded, in

¹ The same remark will apply to this triangle as was made about the inferior carotid triangle. The structures enumerated as contained in the back part of the space lie, strictly speaking, beneath the muscles which form the posterior boundary of the triangle; but as it is very important to bear in mind their close relation to the parotid gland and its boundaries (on account of the frequency of surgical operations on this gland), all these parts are spoken of together.

front, by the Sterno-mastoid; behind, by the Trapezius; below, by the Omo-hyoid. Its floor is formed from above downward by the Splenius, Levator anguli scapulæ, and the middle and posterior Scaleni muscles. It is covered by the integument, the Platysma below, the superficial and deep fasciæ; the spinal accessory nerve is directed obliquely across the space from the Sterno-mastoid, which it pierces, to the under surface of the Trapezius; below, the descending branches of the cervical plexus and the transversalis colli artery and vein cross the space. A chain of lymphatic glands is also found running along the posterior border of the Sterno-mastoid, from the mastoid process to the root of the neck.

The **Subclavian**, the smaller of the two posterior triangles, is bounded, above, by the posterior belly of the Omo-hyoid; below, by the clavicle, its base, directed forward, being formed by the Sterno-mastoid. The size of the subclavian triangle varies according to the extent of attachment of the clavicular portion of the Sterno-mastoid and Trapezius muscles, and also according to the height at which the Omo-hyoid crosses the neck above the clavicle. Its height also varies much according to the position of the arm, being much diminished by raising the limb, on account of the ascent of the clavicle, and increased by drawing the arm downward, when that bone is depressed. This space is covered by the integument, the Platysma, the superficial and deep fasciæ, and crossed by the descending branches of the cervical plexus. Just above the level of the clavicle the third portion of the subclavian artery curves outward and downward from the outer margin of the Scalenus anticus, across the first rib, to the axilla. Sometimes this vessel rises as high as an inch and a half above the clavicle, or to any point intermediate between this and its usual level. Occasionally it passes in front of the Scalenus anticus or pierces the fibres of that muscle. The subclavian vein lies behind the clavicle, and is usually not seen in this space; but it occasionally rises as high up as the artery, and has even been seen to pass with that vessel behind the Scalenus anticus. The brachial plexus of nerves lies above the artery, and in close contact with it. Passing transversely behind the clavicle are the suprascapular vessels, and traversing its upper angle in the same direction, the transversalis colli artery and vein. The external jugular vein runs vertically downward behind the posterior border of the Sterno-mastoid, to terminate in the subclavian vein; it receives the transverse cervical and suprascapular veins, which occasionally form a plexus in front of the artery, and a small vein which crosses the clavicle from the cephalic. The small nerve to the Subclavius muscle also crosses this triangle about its middle. A lymphatic gland is also found in the space. Its floor is formed by the first rib with the first digitation of the Serratus magnus.

The Internal Carotid Artery.

The **internal carotid artery** supplies the anterior part of the brain, the eye, and its appendages, and sends branches to the forehead and nose. Its size in the adult is equal to that of the external carotid, though in the child it is larger than that vessel. It is remarkable for the number of curvatures that it presents in different parts of its course. It occasionally has one or two flexures near the base of the skull, whilst in its passage through the carotid canal and along the side of the body of the sphenoid bone it describes a double curvature which resembles the italic letter *s* placed horizontally. These curvatures most probably diminish the velocity of the current of blood, by increasing the extent of surface over which it moves and adding to the amount of impediment produced from friction.

In considering the course and relations of this vessel it may be conveniently divided into four portions: a cervical, petrous, cavernous, and cerebral.

Cervical Portion.—This portion of the internal carotid commences at the bifurcation of the common carotid, opposite the upper border of the thyroid cartilage, and runs perpendicularly upward, in front of the transverse processes of the three upper cervical vertebræ, to the carotid canal in the petrous portion of the temporal bone. It is superficial at its commencement, being contained in the superior

carotid triangle, and lying on the same level as the external carotid, but behind that artery overlapped by the Sterno-mastoid and covered by the deep fascia, Platysma, and integument: it then passes beneath the parotid gland, being crossed by the hypoglossal nerve, the Digastric and Stylo-hyoid muscles, and the occipital and posterior auricular arteries. Higher up, it is separated from the external carotid by the Stylo-glossus and Stylo-pharyngeus muscles, the glosso-pharyngeal nerve, and pharyngeal branch of the pneumogastric. It is in relation, *behind*, with the Rectus capitis anticus major, the superior cervical ganglion of the sympathetic, and superior laryngeal nerve; *externally*, with the internal jugular vein and pneumogastric nerve, the nerve lying on a plane posterior to the artery; *internally*, with the pharynx, tonsil, the superior laryngeal nerve, and ascending pharyngeal artery. At the base of the skull the glosso-pharyngeal, vagus, spinal accessory, and hypoglossal nerves lie between the artery and the internal jugular vein.

PLAN OF THE RELATIONS OF THE INTERNAL CAROTID ARTERY IN THE NECK.

In front.

Skin, superficial and deep fasciæ.
 Platysma.
 Sterno-mastoid.
 Occipital and posterior auricular arteries.
 Hypoglossal nerve.
 Parotid gland.
 Stylo-glossus and Stylo-pharyngeus muscles.
 Glosso-pharyngeal nerve.
 Pharyngeal branch of the pneumogastric.

Externally.

Internal jugular vein.
 Pneumogastric nerve.

Internally.

Pharynx.
 Superior laryngeal nerve.
 Ascending pharyngeal artery.
 Tonsil.

Behind.

Rectus capitis anticus major.
 Sympathetic.
 Superior laryngeal nerve.

Petrous Portion.—When the internal carotid artery enters the canal in the petrous portion of the temporal bone, it first ascends a short distance, then curves forward and inward, and again ascends as it leaves the canal to enter the cavity of the skull between the lingula and petrosal process. In this canal the artery lies at first in front of the cochlea and tympanum; from the latter cavity it is separated by a thin, bony lamella, which is cribriform in the young subject, and often absorbed in old age. Farther forward it is separated from the Gasserian ganglion by a thin plate of bone, which forms the floor of the fossa for the ganglion and the roof of the horizontal portion of the canal. Frequently this bony plate is more or less deficient, and then the ganglion is separated from the artery by fibrous membrane. The artery is separated from the bony wall of the carotid canal by a prolongation of dura mater, and is surrounded by filaments of the carotid plexus, derived from the ascending branch of the superior cervical ganglion of the sympathetic, and a number of small veins.

Cavernous Portion.—The internal carotid artery in this part of its course is situated between the layers of the dura mater forming the cavernous sinus, but covered by the lining membrane of the sinus. It at first ascends to the posterior clinoid process, then passes forward by the side of the body of the sphenoid bone, and again curves upward on the inner side of the anterior clinoid process, and perforates the dura mater, forming the roof of the sinus. In this part of its course it is surrounded by filaments of the sympathetic nerve, and has in relation with it externally the sixth nerve.

Cerebral Portion.—Having perforated the dura mater, on the inner side of the anterior clinoid process, the internal carotid passes between the second and third

Surgical Anatomy.—The cervical part of the internal carotid is very rarely wounded. Mr. Cripps, in an interesting paper in the *Medico-Chirurgical Transactions*, compares the rareness of a wound of the internal carotid with one of the external or its branches. It is, however, sometimes injured by a stab or gunshot wound in the neck, or even occasionally by a stab from within the mouth, as when a person receives a thrust from the end of a parasol or falls down with a tobacco-pipe in his mouth. The relation of the internal carotid with the tonsil should be especially remembered, as instances have occurred in which the artery has been wounded during the operation of scarifying the tonsil, and fatal hæmorrhage has supervened. The indications for ligature are wounds, when the vessel should be exposed by a careful dissection and tied above and below the bleeding point; and aneurism, which if non-traumatic may be treated by ligature of the common carotid, but if traumatic in origin by exposing the sac and tying the vessel above and below. The incision for ligature of the cervical portion of the internal carotid should be made along the anterior border of the Sterno-mastoid, from the angle of the jaw to the upper border of the thyroid cartilage. The superficial structures being divided and the Sterno-mastoid defined and drawn outward, the cellular tissue must be carefully separated and the posterior belly of the Digastric and hypoglossal nerve sought for as guides to the vessel. When the artery is found the external carotid should be drawn inward and the Digastric muscles upward, and the aneurism needle passed from without inward.

The branches given off from the internal carotid are—

<i>From the Petrous portion</i>	Tympanic (internal or deep).
<i>From the Cavernous portion</i>	{ Arteriæ Receptaculi.
	{ Anterior Meningeal.
	{ Ophthalmic.
<i>From the Cerebral portion</i>	{ Anterior Cerebral.
	{ Middle Cerebral.
	{ Posterior Communicating.
	{ Anterior Choroid.

The cervical portion of the internal carotid gives off no branches.

The **tympanic** is a small branch which enters the cavity of the tympanum through a minute foramen in the carotid canal, and anastomoses with the tympanic branch of the internal maxillary, and with the stylo-mastoid artery.

The **arteriæ receptaculi** are numerous small vessels, derived from the internal carotid in the cavernous sinus; they supply the pituitary body, the Gasserian ganglion, and the walls of the cavernous and inferior petrosal sinuses. Some of these branches anastomose with branches of the middle meningeal.

The **anterior meningeal** is a small branch which passes over the lesser wing of the sphenoid to supply the dura mater of the anterior fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

The **Ophthalmic Artery** arises from the internal carotid, just as that vessel is emerging from the cavernous sinus, on the inner side of the anterior clinoid process, and enters the orbit through the optic foramen, below and on the outer side of the optic nerve. It then passes over the nerve to the inner wall of the orbit, and thence horizontally forward, beneath the lower border of the Superior oblique muscle, to a point behind the internal angular process of the frontal bone, where it divides into two terminal branches, the *frontal* and *nasal*. As the artery crosses the optic nerve it is accompanied by the nasal nerve, and is separated from the frontal nerve by the Rectus superior and Levator palpebræ superioris muscles.

Branches.—The branches of this vessel may be divided into an *orbital group*, which are distributed to the orbit and surrounding parts, and an *ocular group*, which supply the muscles and globe of the eye:

Orbital Group.

Lachrymal.
Supra-orbital.
Posterior Ethmoidal.
Anterior Ethmoidal.
Internal Palpebral.
Frontal.
Nasal.

Ocular Group.

Short Ciliary.
Long Ciliary.
Anterior Ciliary.
Arteria Centralis Retinæ.
Muscular.

The **lachrymal** is one of the largest branches derived from the ophthalmic, arising close to the optic foramen; not infrequently it is given off from the artery before it enters the orbit. It accompanies the lachrymal nerve along the upper border of the External rectus muscle, and is distributed to the lachrymal gland. Its terminal branches, escaping from the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the *external palpebral*; they run inward in the upper and lower lids

FIG. 290.—The ophthalmic artery and its branches, the roof of the orbit having been removed.

respectively, and anastomose with the internal palpebral arteries, forming an arterial circle in this situation. The lachrymal artery gives off one or two *malar branches*, one of which passes through a foramen in the malar bone, to reach the temporal fossa, and anastomoses with the deep temporal arteries; the other appears on the cheek through the malar foramen, and anastomoses with the transverse facial. A branch is also sent backward through the sphenoidal fissure to the dura mater, which anastomoses with a branch of the middle meningeal artery.

Peculiarities.—The lachrymal artery is sometimes derived from one of the anterior branches of the middle meningeal artery.

The **supra-orbital artery** arises from the ophthalmic as that vessel is crossing over the optic nerve. Ascending so as to arise above all the muscles of the orbit, it passes forward, with the supra-orbital nerve, between the periosteum and Levator palpebræ; and, passing through the supra-orbital foramen, divides into a superficial and deep branch, which supply the integument, the muscles, and the pericranium of the forehead, anastomosing with the frontal, the anterior branch of the temporal, and the artery of the opposite side. This artery in the orbit supplies the Superior rectus and the Levator palpebræ, and sends a branch inward, across the pulley of the Superior oblique muscle, to supply the parts at the inner canthus. At the supra-orbital foramen it frequently transmits a branch to the diploë.

The **ethmoidal branches** are two in number—posterior and anterior. The

former, which is the smaller, passes through the posterior ethmoidal foramen, supplies the posterior ethmoidal cells, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater, and nasal branches which descend into the nose through apertures in the cribriform plate, anastomosing with branches of the sphenopalatine. The anterior ethmoidal artery accompanies the nasal nerve through the anterior ethmoidal foramen, supplies the

FIG. 291.—The arteries of the base of the brain. The right half of the cerebellum and pons have been removed.

N.B.—It will be noticed that in the illustration the two anterior cerebral arteries have been drawn at a considerable distance from each other: this makes the anterior communicating artery appear very much longer than it really is.

anterior ethmoidal cells and frontal sinuses, and, entering the cranium, gives off a meningeal branch, which supplies the adjacent dura mater and nasal branches, which descend into the nose, through the slit by the side of the crista galli, and, running along the groove on the under surface of the nasal bone, supply the skin of the nose.

The **palpebral arteries**, two in number, superior and inferior, arise from the ophthalmic, opposite the pulley of the Superior oblique muscle; they leave the orbit to encircle the eyelids near their free margin, forming a superior and an inferior arch, which lie between the Orbicularis muscle and tarsal plates; the superior palpebral inosculating at the outer angle of the orbit with the orbital branch of the temporal artery, and with the upper of the two external palpebral branches from the lachrymal artery—the inferior palpebral inosculating, at the outer angle of the orbit, with the lower of the two external palpebral branches from the lachrymal and with the transverse facial arteries, and at the inner side of the lid with a branch from the angular artery. From this last anastomosis a branch passes to the nasal duct, ramifying in its mucous membrane, as far as the inferior meatus.

FIG. 292.—Vascular area of the upper surface of the cerebrum. (After Duret.) I. The part supplied by the external and inferior frontal artery. II. The part supplied by the ascending frontal. III. The part supplied by the ascending parietal. IV. The part supplied by the parieto-sphenoidal artery.

The **frontal artery**, one of the terminal branches of the ophthalmic, passes from the orbit at its inner angle, and, ascending on the forehead, supplies the integument, muscles, and pericranium, anastomosing with the supraorbital artery and with the artery of the opposite side.

The **nasal artery**, the other terminal branch of the ophthalmic, emerges from the orbit above the tendo oculi, and, after giving a branch to the upper part of the lachrymal sac, divides into two branches, one of which crosses the root of the nose, the *transverse nasal*, and anastomoses with the angular artery; the

other, the *dorsalis nasi*, runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side and with the lateral nasal branch of the facial.

The **ciliary arteries** are divisible into three groups, the short, long, and anterior. The *short ciliary arteries*, from six to twelve in number, arise from the ophthalmic or some of its branches; they surround the optic nerve as they pass forward to the posterior part of the eyeball, pierce the sclerotic coat around the entrance of the nerve, and supply the choroid coat and ciliary processes. The *long ciliary arteries*, two in number, pierce the posterior part of the sclerotic at some little distance from the optic nerve, and run forward, along each side of the eyeball, between the sclerotic and choroid, to the ciliary muscle, where they divide into two branches; these form an arterial circle, the *circulus major*, around the circumference of the iris, from which numerous radiating branches pass forward, in its substance, to its free margin, where they form a second arterial circle, the *circulus minor*, around its pupillary margin. The *anterior ciliary arteries* are derived from the muscular branches; they pass to the front of the

FIG. 293.—Vascular area of the internal surface of the cerebrum. (After Duret.) I. The part supplied by the anterior and internal frontal. II. The part supplied by the middle and internal frontal. III. The part supplied by the posterior and internal frontal. IV. The part supplied by the posterior temporal; and V. The part supplied by the occipital, both terminal branches of the posterior cerebral.

eyeball in company with the tendons of the Recti muscles, form a vascular zone beneath the conjunctiva, and then pierce the sclerotic a short distance from the cornea and terminate in the *circulus major* of the iris.

The **arteria centralis retinæ** is the first and one of the smallest branches of the ophthalmic artery. It runs for a short distance within the dural sheath of the nerve, but about half an inch behind the eyeball it pierces the optic nerve obliquely, and runs forward in the centre of its substance, and enters the globe of the eye through the *porus opticus*. Its mode of distribution will be described in the account of the anatomy of the eye.

The **muscular branches**, two in number, superior and inferior, frequently spring from a common trunk. The superior, the smaller, often wanting, supplies the Levator palpebræ, Superior rectus, and Superior oblique. The inferior, more constant in its existence, passes forward, between the optic nerve and Inferior rectus, and is distributed to the External, Internal, and Inferior recti, and Inferior oblique. This vessel gives off most of the anterior ciliary arteries. Additional muscular branches are given off from the lachrymal and supra-orbital arteries or from the ophthalmic itself.

The *anterior cerebral* arises from the internal carotid at the inner extremity of the fissure of Sylvius. It passes forward and inward across the anterior perforated space, above the optic nerve, to the commencement of the great longitudinal fissure. Here it comes into close relationship with the artery of the opposite side, and the two vessels are connected together by a short anastomosing trunk, about two lines in length, the *anterior communicating* artery. From this point the two vessels run side by side in the longitudinal fissure, curve round the genu of the corpus callosum, and, turning backward, continue along its upper surface to its posterior part, where they terminate by anastomosing with the posterior cerebral arteries. In their course they give off the following branches:

Antero-median ganglionic.

Anterior internal frontal.

Inferior internal frontal.

Middle internal frontal.

Posterior internal frontal.

The *antero-median ganglionic* is a group of small arteries which arise at the commencement of the anterior cerebral artery; they pierce the anterior perforated space and lamina cinerea, and supply the head of the caudate nucleus.

FIG. 294.—Vascular area of the inferior surface of the cerebrum. (After Duret.) I. The part supplied by the anterior temporal artery. II. The part supplied by the posterior temporal artery. III. The part supplied by the occipital artery.

The *inferior internal frontal*, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus, and internal orbital convolution.

The *anterior internal frontal* branches supply a part of the marginal convolution, and send branches over the edge of the hemisphere to the superior and middle frontal convolutions and upper part of the ascending frontal convolution. The *middle internal frontal* branches supply the corpus callosum, the convolution of the corpus callosum, the inner surface of the first frontal convolution, and the

upper part of the ascending frontal convolution. The *posterior internal frontal branches* supply the lobus quadratus and adjacent outer surface of the hemisphere.

The **anterior communicating artery** is a short branch, about two lines in length, but of moderate size, connecting together the two anterior cerebral arteries across the longitudinal fissure. Sometimes this vessel is wanting, the two arteries joining together to form a single trunk, which afterward divides. Or the vessel may be wholly or partially divided into two; frequently it is longer and smaller than usual. It gives off some of the antero-median ganglionic group of vessels, which are, however, principally derived from the anterior cerebral.

The **middle cerebral artery** (Fig. 295), the largest branch of the internal carotid, passes obliquely outward along the fissure of Sylvius, and opposite the island of Reil divides into its terminal branches. The branches of the middle cerebral artery are—

Antero-lateral ganglionic.
Inferior external frontal.

Ascending frontal.
Ascending parietal.

Parieto-temporal.

The *antero-lateral ganglionic branches* are a group of small arteries which arise at the commencement of the middle cerebral artery; they pierce the anterior perforated space and supply the greater part of the caudate nucleus, the lenticular nucleus, the internal capsule, and a part of the optic thalamus. One artery of this group is of larger size than the rest, and is of special importance, as being the artery in the brain most frequently ruptured; it has been termed by Charcot the "*artery of cerebral hemorrhage*." It passes up between the lenticular nucleus and the external capsule, and ultimately ends in the caudate nucleus. The *inferior external frontal* supplies the third or inferior frontal convolution (Broca's convolution) and the outer part of the orbital surface of the frontal lobe. The *ascending frontal* supplies the ascending frontal convolution. The *ascending parietal* supplies the ascending parietal convolution and the lower part of the superior parietal convolution. The *parieto-temporal* supplies the supra-marginal, the superior, and part of the middle temporal convolutions, and the angular gyrus.

The **posterior communicating artery** arises from the back part of the internal carotid, runs directly backward, and anastomoses with the posterior cerebral, a

FIG. 295.—The distribution of the middle cerebral artery. (After Charcot.)

branch of the basilar. This artery varies considerably in size, being sometimes small, and occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently

posterior cerebrals. Each of these principal arteries gives origin to two very different systems of secondary vessels. One of these systems has been named the *central ganglionic system*, and the vessels belonging to it supply the central ganglia of the brain; the other has been named the *cortical arterial system*, and its vessels ramify in the pia mater and supply the cortex and subjacent medullary matter. These two systems, though they have a common origin, do not communicate at any point of their peripheral distribution, and are entirely independent of each other. Though some of the arteries of the cortical system approach, at their terminations, the regions supplied by the central ganglionic system, no communication between the two sets of vessels takes place, and there is between the parts supplied by the two systems a borderland of diminished nutritive activity, where, it is said, softening is especially liable to occur in the brains of old people.

The Central Ganglionic System.—All the vessels belonging to this system are given off from the circle of Willis or from the vessels immediately after their origin

FIG. 297.—Distribution of the cortical arteries. (After Charcot.) 1. Medullary arteries. 1'. Group of medullary arteries in the sulcus between two adjacent convolutions. 1''. Arteries situated among the short association fibres. 2. Cortical arteries. a. Capillary network with fairly wide meshes, situated beneath the pia mater. b. Network with more compact, polygonal meshes, situated in the cortex. c. Transitional network with wider meshes. d. Capillary network in the white matter.

from it, so that if a circle is drawn at a distance of about an inch from the circle of Willis, it will include the origin of all the arteries belonging to this system (Fig. 296). The vessels of this system form six principal groups: (I.) the *antero-median group*, derived from the anterior cerebrals and anterior communicating; (II.) the *postero-median group*, from the posterior cerebrals and posterior communicating; (III.) the right and left *antero-lateral group*, from the middle cerebrals; and (IV.) the right and left *postero-lateral group*, from the posterior cerebrals, after they have wound round the crura cerebri. The vessels belonging to this system are larger than those of the cortical system, and are what Cohnheim has termed “terminal” arteries; that is to say, vessels which from their origin to their termination neither supply nor receive any anastomotic branch, so that by one of the small vessels only a limited area of the central ganglia can be injected; and the injection cannot be driven beyond the area of the part supplied by the particular vessel which is the subject of the experiment.

The Cortical Arterial System.—The vessels forming this system are the terminal branches of the anterior, middle, and posterior cerebral arteries, described above.

These vessels divide and ramify in the substance of the pia mater, and give off nutrient arteries which penetrate the cortex perpendicularly. These nutrient vessels are divisible into two classes—the long and short. The *long*—or, as they are sometimes called, the *medullary*—arteries pass through the gray matter to penetrate the centrum ovale to the depth of about an inch and a half, without intercommunicating otherwise than by very fine capillaries, and thus constitute so many independent small systems. The *short vessels* are confined to the cortex, where they form with the long vessels a compact network in the middle zone of the gray matter, the outer and inner zones being sparingly supplied with blood (Fig. 297). The vessels of the cortical arterial system are not so strictly “terminal” as those of the central ganglionic system, but they approach this type very closely, so that injection of one area from the vessel of another area, though it may be possible, is frequently very difficult, and is only effected through vessels of small calibre. As a result of this, obstruction of one of the main branches or its divisions may have the effect of producing softening in a very limited area of the cortex.¹

ARTERIES OF THE UPPER EXTREMITY.

The artery which supplies the upper extremity continues as a single trunk from its commencement down to the elbow, but different portions of it have received different names according to the region through which it passes. That part of the vessel which extends from its origin to the outer border of the first rib is termed the subclavian; beyond this point to the lower border of the axilla it is termed the axillary; and from the lower margin of the axillary space to the bend of the elbow it is termed brachial; here the single trunk terminates by dividing into two branches, the radial and ulnar—an arrangement precisely similar to what occurs in the lower limb.

THE SUBCLAVIAN ARTERIES (Fig. 298).

The **subclavian artery** on the right side arises from the innominate artery opposite the right sterno-clavicular articulation; on the left side it arises from the arch of the aorta. It follows, therefore, that these two vessels must, in the first part of their course, differ in their length, their direction, and their relation with neighboring parts.

In order to facilitate the description of these vessels, more especially from a surgical point of view, each subclavian artery has been divided into three parts. The first portion, on the right side, passes upward and outward from the origin of the vessel to the inner border of the *Scalenus anticus*. On the left side it ascends nearly vertically, to gain the inner border of that muscle. The second part passes outward, behind the *Scalenus anticus*; and the third part passes from the outer margin of that muscle, beneath the clavicle, to the outer border of the first rib, where it becomes the axillary artery. The first portion of these two vessels differs so much in its course and in its relation with neighboring parts that it will be described separately. The second and third parts are alike on the two sides.

FIRST PART OF THE RIGHT SUBCLAVIAN ARTERY (Figs. 280, 283, 298).

The **right subclavian artery** arises from the *arteria innominata*, opposite the upper part of the right sterno-clavicular articulation, and passes upward and outward to the inner margin of the *Scalenus anticus* muscle. In this part of its course it ascends a little above the clavicle, the extent to which it does so varying in different cases. It is covered, *in front*, by the integument, superficial fascia, *Platysma*, deep fascia, the clavicular origin of the *Sterno-mastoid*, the *Sterno-*

¹ The student who desires further information on this subject is referred to Charcot's *Localization of Cerebral and Spinal Diseases*, p. 42 *et seq.*, whence the facts above given have been principally derived.

hyoid, and Sterno-thyroid muscles, and another layer of the deep fascia. It is crossed by the internal jugular and vertebral veins, and by the pneumogastric and the cardiac branches of the sympathetic. A loop of the sympathetic nerve itself also crosses the artery, forming a ring around the vessels. The anterior jugular vein passes outward in front of the artery but is not in contact with it, being separated from it by the Sterno-hyoid and Sterno-thyroid muscles. Below and behind the artery is the pleura, which separates it from the apex of the lung; behind is the cord of the sympathetic nerve; the recurrent laryngeal nerve winds round the lower and back part of the vessel.

FIG. 298.—The subclavian artery, showing its relations. (From a preparation in the Museum of the Royal College of Surgeons of England.)

PLAN OF RELATIONS OF FIRST PORTION OF THE RIGHT SUBCLAVIAN ARTERY.

In front.

Skin, superficial fascia.
 Platysma, deep fascia.
 Clavicular origin of Sterno-mastoid.
 Sterno-hyoid and Sterno-thyroid.
 Anterior jugular, Internal jugular, and vertebral veins.
 Pneumogastric and cardiac nerves.
 Loop from the sympathetic.

Beneath.
Pleura.
Recurrent laryngeal nerve.

Behind.
Recurrent laryngeal nerve.
Sympathetic.
Pleura and apex of lung.

FIRST PART OF THE LEFT SUBCLAVIAN ARTERY (Fig. 280).

The **left subclavian artery** arises from the end of the arch of the aorta, opposite the fourth dorsal vertebra, and ascends nearly vertically to the inner margin of the *Scalenus anticus* muscle. This part of the vessel is, therefore, longer than the right, situated deeply in the cavity of the chest, and directed nearly vertically upward, instead of arching outward like the vessel of the opposite side.

It is in relation, *in front*, with the pneumogastric, cardiac, and phrenic nerves, which lie parallel with it, the left carotid artery, left internal jugular and vertebral veins, and the commencement of the left innominate vein, and is covered by the *Sterno-thyroid*, *Sterno-hyoid*, and *Sterno-mastoid* muscles; *behind*, it is in relation with the *œsophagus*, thoracic duct, inferior cervical ganglion of the sympathetic, and *Longus colli*; higher up, however, the *œsophagus* and thoracic duct lie to its right side; the latter ultimately arching over the vessel to join the angle of union between the subclavian and internal jugular veins. To its *inner side* are the *œsophagus*, trachea, and thoracic duct; to its *outer side*, the left pleura and lung.

SECOND AND THIRD PARTS OF THE SUBCLAVIAN ARTERY (Figs. 283, 298).

The **Second Portion of the Subclavian Artery** lies behind the *Scalenus anticus* muscle; it is very short, and forms the highest part of the arch described by that vessel.

Relations.—It is covered, *in front*, by the skin, superficial fascia, *Platysma*, deep cervical fascia, *Sterno-mastoid*, and the *Scalenus anticus* muscle. On the right side the phrenic nerve is separated from the second part of the artery by the *Anterior scalene* muscle, while on the left side the nerve crosses the first part of the artery immediately to the inner edge of the muscle. *Behind*, it is in relation with the pleura and the *Middle scalene*. *Above*, with the brachial plexus of nerves. *Below*, with the pleura. The subclavian vein lies below and in front of the artery, separated from it by the *Scalenus anticus*.

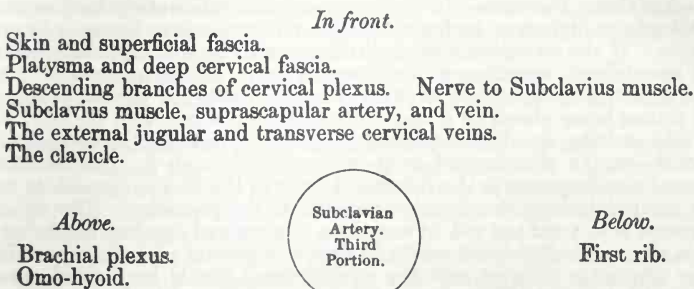

PLAN OF RELATIONS OF SECOND PORTION OF SUBCLAVIAN ARTERY.

The **Third Portion of the Subclavian Artery** passes downward and outward from the outer margin of the Scalenus anticus to the outer border of the first rib, where it becomes the axillary artery. This portion of the vessel is the most superficial, and is contained in a subclavian triangle (see page 502).

Relations.—It is covered, in *front*, by the skin, the superficial fascia, the Platysma, the descending claviclar branches of the cervical plexus, and the deep cervical fascia; by the clavicle, the Subclavius muscle, and the suprascapular artery and vein, and the transverse cervical vein; the nerve to the Subclavius muscle passes vertically downward in front of the artery. The external jugular vein crosses it at its inner side, and receives the suprascapular and transverse cervical veins, which frequently form a plexus in front of it. The subclavian vein is below and in front of the artery, lying close behind the clavicle. *Behind*, it lies on the Middle scalene muscle and the lowest cord of the brachial plexus, formed by the union of the last cervical and first dorsal nerves. *Above* it, and to its outer side, is the brachial plexus and Omo-hyoid muscle. *Below*, it rests on the upper surface of the first rib.

PLAN OF RELATIONS OF THIRD PORTION OF SUBCLAVIAN ARTERY.

Peculiarities.—The subclavian arteries vary in their origin, their course, and the height to which they rise in the neck.

The *origin* of the right subclavian from the innominate takes place, in some cases, above the sterno-clavicular articulation, and occasionally, but less frequently, in the cavity of the thorax, below that joint. Or the artery may arise as a separate trunk from the arch of the aorta. In such cases it may be either the first, second, third, or even the last branch derived from that vessel; in the majority of cases it is the first or last, rarely the second or third. When it is the first branch, it occupies the ordinary position of the innominate artery; when the second or third, it gains its usual position by passing behind the right carotid; and when the last branch, it arises from the left extremity of the arch, at its upper or back part, and passes obliquely toward the

right side, usually behind the trachea, œsophagus, and right carotid, sometimes between the œsophagus and trachea to the upper border of the first rib, whence it follows its ordinary course. In very rare instances this vessel arises from the thoracic aorta, as low down as the fourth dorsal vertebra. Occasionally it perforates the anterior Scalenus; more rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the Anterior Scalenus. The artery may ascend as high as an inch and a half above the clavicle or any intermediate point between this and the upper border of the bone, the right subclavian usually ascending higher than the left.

The left subclavian is occasionally joined at its origin with the left carotid.

Surface Marking.—The course of the subclavian artery in the neck may be mapped out by describing a curve, with its convexity upward at the base of the posterior triangle. The inner end of this curve corresponds to the sterno-clavicular joint, the outer end to the centre of the lower border of the clavicle. The curve is to be drawn with such an amount of convexity that its mid-point reaches half an inch above the upper border of the clavicle. The left subclavian artery is more deeply placed than the right in the first part of its course, and, as a rule, does not reach quite as high a level in the neck. It should be borne in mind that the posterior border of the Sterno-mastoid muscle corresponds to the outer border of the Scalenus anticus, so that the third portion of the artery, that part most accessible for operation, lies immediately external to the posterior border of the Sterno-mastoid.

Surgical Anatomy.—The relations of the subclavian arteries of the two sides having been examined, the student should direct his attention to a consideration of the best position in which compression of the vessel may be effected, or in what situation a ligature may be best applied in cases of aneurism or wound.

Compression of the subclavian artery is required in cases of operations about the shoulder, in the axilla, or at the upper part of the arm; and the student will observe that there is only one situation in which it can be effectually applied—viz. where the artery passes across the upper surface of the first rib. In order to compress the vessel in this situation, the shoulder should be depressed, and the surgeon, grasping the side of the neck, should press with his thumb in the angle formed by the posterior border of the Sterno-mastoid with the upper border of the clavicle, downward, backward, and inward against the rib; if from any cause the shoulder cannot be sufficiently depressed, pressure may be made from before backward, so as to compress the artery against the middle Scalenus and transverse process of the seventh cervical vertebra. In appropriate cases, a preliminary incision may be made through the cervical fascia, and the finger may be pressed down directly upon the artery.

Ligature of the subclavian artery may be required in cases of wounds or of aneurism in the axilla, or in cases of aneurism on the cardiac side of the point of ligature; and the third part of the artery is that which is most favorable for an operation, on account of its being comparatively superficial and most remote from the origin of the large branches. In those cases where the clavicle is not displaced, this operation may be performed with comparative facility; but where the clavicle is pushed up by a large aneurismal tumor in the axilla the artery is placed at a great depth from the surface, which materially increases the difficulty of the operation. Under these circumstances it becomes a matter of importance to consider the height to which this vessel reaches above the bone. In ordinary cases its arch is about half an inch above the clavicle, occasionally as high as an inch and a half, and sometimes so low as to be on a level with its upper border. If the clavicle is displaced, these variations will necessarily make the operation more or less difficult according as the vessel is more or less accessible.

The chief points in the operation of tying the third portion of the subclavian artery are as follows: The patient being placed on a table in the supine position, with the head drawn over to the opposite side and the shoulder depressed as much as possible, the integument should be drawn downward over the clavicle, and an incision made through it, upon that bone, from the anterior border of the Trapezius to the posterior border of the Sterno-mastoid, to which may be added a short vertical incision meeting the inner end of the preceding. The object in drawing the skin downward is to avoid any risk of wounding the external jugular vein, for as it perforates the deep fascia above the clavicle, it cannot be drawn downward with the skin. The soft parts should now be allowed to glide up, and the cervical fascia should be divided upon a director, and if the interval between the Trapezius and Sterno-mastoid muscles be insufficient for the performance of the operation, a portion of one or both may be divided. The external jugular vein will now be seen toward the inner side of the wound: this and the suprascapular and transverse cervical veins, which terminate in it, should be held aside. If the external jugular vein is at all in the way and exposed to injury, it should be tied in two places and divided. The suprascapular artery should be avoided, and the Omo-hyoid muscle held aside if necessary. In the space beneath this muscle careful search must be made for the vessel: a deep layer of fascia and some connective tissue having been divided carefully, the outer margin of the Scalenus anticus muscle must be felt for, and, the finger being guided by it to the first rib, the pulsation of the subclavian artery will be felt as it passes over the rib. The sheath of the vessels having been opened, the aneurism needle may then be passed around the artery from above downward and inward, so as to avoid including any of the branches of the brachial plexus. If the clavicle is so raised by the tumor that the application of the ligature cannot be effected in this situation, the artery may be tied above the first rib, or even behind the Scalenus anticus muscle; the difficulties of the operation in such a case will be materially increased, on account of the greater depth of the artery and the alteration in position of the surrounding parts.

The second part of the subclavian artery, from being that portion which rises highest in the neck, has been considered favorable for the application of the ligature when it is difficult to tie the artery in the third part of its course. There are, however, many objections to the operation in this situation. It is necessary to divide the *Scalenus anticus* muscle, upon which lies the phrenic nerve, and at the inner side of which is situated the internal jugular vein; and a wound of either of these structures might lead to the most dangerous consequences. Again, the artery is in contact, below, with the pleura, which must also be avoided; and, lastly, the proximity of so many of its large branches arising internal to this point must be a still further objection to the operation. In cases, however, where the sac of an axillary aneurism encroaches on the neck, it may be necessary to divide the outer half or two-thirds of the *Scalenus anticus* muscle, so as to place the ligature on the vessel at a greater distance from the sac. The operation is performed exactly in the same way as ligature of the third portion, until the *Scalenus anticus* is exposed, when it is to be divided on a director (never to a greater extent than its outer two-thirds), and it immediately retracts. The operation is therefore merely an extension of ligature of the third portion of the vessel.

In those cases of aneurism of the axillary or subclavian artery which encroach upon the outer portion of the *Scalenus* muscle to such an extent that a ligature cannot be applied in that situation, it may be deemed advisable, as a last resource, to tie the first portion of the subclavian artery. On the left side this operation is almost impracticable; the great depth of the artery from the surface, its intimate relation with the pleura, and its close proximity to the thoracic duct and to so many important veins and nerves, present a series of difficulties which it is next to impossible to overcome.¹ On the right side the operation is practicable, and has been performed, though never with success. The main objection to the operation in this situation is the smallness of the interval which usually exists between the commencement of the vessel and the origin of the nearest branch. The operation may be performed in the following manner: The patient being placed on the table in the supine position with the neck extended, an incision should be made along the upper border of the inner part of the clavicle, and a second along the inner border of the *Sterno-mastoid*, meeting the former at an angle. The attachment of both heads of the *Sterno-mastoid* must be divided on a director and turned outward; a few small arteries and veins, and occasionally the anterior jugular, must be avoided, or, if necessary, ligatured in two places and divided, and the *Sterno-hyoid* and *Sterno-thyroid* muscles divided in the same manner as the preceding muscle. After tearing through the deep fascia with the finger-nail, the internal jugular vein will be seen crossing the subclavian artery; this should be pressed aside and the artery secured by passing the needle from below upward, by which the pleura is more effectually avoided. The exact position of the vagus nerve, the recurrent laryngeal, the phrenic and sympathetic nerves should be remembered, and the ligature should be applied near the origin of the vertebral, in order to afford as much room as possible for the formation of a coagulum between the ligature and the origin of the vessel. It should be remembered that the right subclavian artery is occasionally deeply placed in the first part of its course when it arises from the left side of the aortic arch, and passes in such cases behind the œsophagus or between it and the trachea.

Collateral Circulation.—After ligature of the third part of the subclavian artery the collateral circulation is mainly established by three sets of vessels, thus described in a dissection:

"1. A posterior set, consisting of the suprascapular and posterior scapular branches of the subclavian, anastomosing with the subscapular from the axillary.

"2. An internal set produced by the connection of the internal mammary on the one hand, with the superior and long thoracic arteries, and the branches from the subscapular on the other.

"3. A middle or axillary set, which consisted of a number of small vessels derived from branches of the subclavian, above, and, passing through the axilla, terminated either in the main trunk or some of the branches of the axillary below. This last set presented most conspicuously the peculiar character of newly-formed or, rather, dilated arteries, being excessively tortuous, and forming a complete plexus.

"The chief agent in the restoration of the axillary artery below the tumor was the subscapular artery, which communicated most freely with the internal mammary, suprascapular, and posterior scapular branches of the subclavian, from all of which it received so great an influx of blood as to dilate it to three times its natural size."²

When a ligature is applied to the first part of the subclavian artery, the collateral circulation is carried on by—1, the anastomosis between the superior and inferior thyroid; 2, the anastomosis of the two vertebrals; 3, the anastomosis of the internal mammary with the deep epigastric and the aortic intercostals; 4, the superior intercostal anastomosing with the aortic intercostals; 5, the profunda cervicis anastomosing with the princeps cervicis; 6, the scapular branches of the thyroid axis anastomosing with the branches of the axillary; and 7, the thoracic branches of the axillary anastomosing with the aortic intercostals.

¹ The operation was, however, performed in New York by Dr. J. K. Rodgers, and the case is related in *A System of Surgery*, edited by T. Holmes, 2d ed., vol. iii., pp. 620, etc.

² *Guy's Hospital Reports*, vol. i., 1836: case of axillary aneurism, in which Mr. Aston Key had tied the subclavian artery on the outer edge of the *Scalenus* muscle twelve years previously.

Branches.—The branches given off from the subclavian artery are:

Vertebral.

Internal mammary.

Thyroid axis.

Superior intercostal.

On the left side all four branches generally arise from the first portion of the vessel; but on the right side, the superior intercostal usually arises from the second portion of the vessel. On both sides of the body the first three branches arise close together at the inner margin of the *Scalenus anticus*; in the majority of cases, a free interval of from half an inch to an inch exists between the commencement of the artery and the origin of the nearest branch; in a smaller number of cases, an interval of more than an inch exists, but it never exceeds an inch and three-quarters. In a very few instances, the interval has been found to be less than half an inch. The vertebral artery arises from the upper and posterior part of the artery, the internal mammary from the lower part of the artery; the thyroid axis from in front, and the superior intercostal from behind.

FIG. 299.—Plan of the branches of the right subclavian artery.

The **Vertebral Artery** (Fig. 289) is generally the first and largest branch of the subclavian; it arises from the upper and back part of the first portion of the vessel, and, passing upward, enters the foramen in the transverse process of the sixth cervical vertebra,¹ and ascends through the foramina in the transverse processes of all the vertebræ above this. Above the upper border of the axis it inclines outward and upward to the foramen in the transverse process of the atlas, through which it passes; it then winds backward behind its articular process, runs in a deep groove on the upper surface of the posterior arch of this bone, and, passing beneath the posterior occipito-atlantal ligament, pierces the dura mater and arachnoid, and enters the skull through the foramen magnum. It then passes forward and upward, inclining from the lateral aspect to the front of the medulla oblongata. It unites in the middle line with the vessel of the opposite side at the lower border of the pons Varolii to form the *basilar artery*.

Relations.—At its origin, it is situated behind the internal jugular and vertebral veins, and is crossed by the inferior thyroid artery: it lies between the *Longus colli* and *Scalenus anticus* muscles, having the thoracic duct in front of it on the left side. It rests on the transverse process of the seventh cervical vertebra and the sympathetic nerve. Within the foramina formed by the transverse processes of the vertebræ it is accompanied by a plexus of nerves from the inferior cervical ganglion of the sympathetic, and is surrounded by a dense plexus of veins which unite to form the vertebral vein at the lower part of the neck. It is situated in front of the cervical nerves, as they issue from the intervertebral foramina. While winding round the articular process of the atlas, it is contained in a triangular space (*suboccipital triangle*) formed by the *Rectus capitis posticus major*, the *Superior* and *Inferior oblique* muscles; and at this point is covered by the *Complexus* muscle. The suboccipital nerve here lies between the artery and the bone. Within the skull, as it winds round the medulla oblongata, it is placed between the hypoglossal nerve and the anterior root of the suboccipital nerve, beneath the first digitation of the *ligamentum denticulatum*, and finally ascends between the basilar process of the occipital bone and the anterior surface of the medulla oblongata.

¹ The vertebral artery sometimes enters the foramen in the transverse process of the fifth vertebra. Dr. Snyth, who tied this artery in the living subject, found it, in one of his dissections, passing into the foramen in the seventh vertebra.

Branches.—These may be divided into two sets—those given off in the neck and those within the cranium.

Cervical Branches.

Lateral Spinal.
Muscular.

Cranial Branches.

Posterior Meningeal.
Anterior Spinal.
Posterior Spinal.
Posterior Inferior Cerebellar.
Bulbar.

The **lateral spinal branches** enter the spinal canal through the intervertebral foramina and divide into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the artery above and below, so that two lateral anastomotic chains are formed on the posterior surface of the bodies of the vertebræ near the attachment of the pedicles. From these anastomotic chains branches are given off to supply the periosteum and the bodies of the vertebræ, and to communicate with similar branches from the opposite side; from these latter small branches are given off which join similar branches above and below, so that a central anastomotic chain is formed on the posterior surface of the bodies of the vertebræ.

Muscular branches are given off to the deep muscles of the neck, where the vertebral artery curves round the articular process of the atlas. They anastomose with the occipital and with the ascending and deep cervical arteries.

The **posterior meningeal** are one or two small branches given off from the vertebral opposite the foramen magnum. They ramify between the bone and dura mater in the cerebellar fossæ, and supply the falx cerebelli.

The **anterior spinal** is a small branch which arises near the termination of the vertebral, and, descending in front of the medulla oblongata, unites with its fellow of the opposite side at about the level of the foramen magnum. One of these vessels is usually larger than the other, but occasionally they are about equal in size. The single trunk thus formed descends on the front of the spinal cord, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina; these branches are derived from the vertebral and ascending cervical of the inferior thyroid in the neck; from the intercostal in the dorsal region; and from the lumbar, ilio-lumbar, and lateral sacral arteries in the lower part of the spine. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord. This vessel is placed in the pia mater along the anterior median fissure; it supplies that membrane and the substance of the cord, and sends off branches at its lower part to be distributed to the cauda equina, and ends on the central fibrous prolongation of the cord.

The **posterior spinal** arises from the vertebral at the side of the medulla oblongata: passing backward to the posterior aspect of the spinal cord, it descends on each side, lying behind the posterior roots of the spinal nerves, and is reinforced by a succession of small branches which enter the spinal canal through the intervertebral foramina, and by which it is continued to the lower part of the cord and to the cauda equina. Branches from these vessels form a free anastomosis round the posterior roots of the spinal nerves, and communicate, by means of very tortuous transverse branches, with the vessel of the opposite side. At its commencement it gives off an ascending branch, which terminates on the side of the fourth ventricle.

The **posterior inferior cerebellar artery** (Fig. 291), the largest branch of the vertebral, winds backward round the upper part of the medulla oblongata, passing between the origin of the pneumogastric and spinal accessory nerves, over the restiform body to the under surface of the cerebellum, where it divides into two

branches—an internal one, which is continued backward to the notch between the two hemispheres of the cerebellum; and an external one, which supplies the under surface of the cerebellum as far as its outer border, where it anastomoses with the anterior inferior cerebellar and the superior cerebellar branches of the basilar artery. Branches from this artery supply the choroid plexus of the fourth ventricle.

The **bulbar arteries** comprise several minute vessels which spring from the vertebral and its branches and are distributed to the medulla oblongata.

Surgical Anatomy.—The vertebral artery has been tied in several instances: 1, for wounds or traumatic aneurism; 2, after ligation of the innominate, either at the same time to prevent hemorrhage, or later on to arrest bleeding where it has occurred at the seat of ligature; and 3, in epilepsy. In these latter cases the treatment has been recommended by Dr. Alexander, of Liverpool, in the hope that by diminishing the supply of blood to the posterior part of the brain and the spinal cord a diminution or cessation of the epileptic fits would result. But, on account of the uncertainty as to what cases, if any, derived benefit from the operation, it has now been abandoned. The operation of ligation of the vertebral is performed by making an incision along the posterior border of the Sterno-mastoid muscle, just above the clavicle. The muscle is pulled to the inner side, and the anterior tubercle of the transverse process of the sixth cervical vertebra sought for. A deep layer of fascia being now divided, the interval between the Scalenus anticus and the Longus colli just below their attachment to the tubercle is defined, and the artery and vein found in the interspace. The vein is to be drawn to the outer side, and the aneurism needle passed from without inward. Drs. Ramskill and Bright have pointed out that severe pain at the back of the head may be symptomatic of disease of the vertebral artery just before it enters the skull. This is explained by the close connection of the artery with the suboccipital nerve in the groove on the posterior arch of the atlas. Disease of the same artery has been also said to affect speech, from pressure on the hypoglossal where it is in relation with the vessel, leading to paralysis of the muscles of the tongue.

The **Basilar Artery** (Fig. 291), so named from its position at the base of the skull, is a single trunk formed by the junction of the two vertebral arteries; it extends from the posterior to the anterior border of the pons Varolii, lying in its median groove, under cover of the arachnoid. It ends by dividing into the two *posterior cerebral arteries*. Its branches are, on each side, the following:

Transverse.	Superior Cerebellar.
Anterior Inferior Cerebellar.	Posterior Cerebral.

The **transverse branches** supply the pons Varolii and adjacent parts of the brain; one branch, the *internal auditory*, accompanies the auditory nerve into the internal auditory meatus.

The **anterior inferior cerebellar artery** passes backward across the crus cerebelli, to be distributed to the anterior border of the under surface of the cerebellum, anastomosing with the posterior inferior cerebellar branch of the vertebral.

The **superior cerebellar arteries** arise near the termination of the basilar. They pass outward, immediately behind the third nerves, which separate them from the posterior cerebral, wind round the crura cerebri, close to the fourth nerve, and, arriving at the upper surface of the cerebellum, divide into branches which ramify in the pia mater and, reaching the circumference of the cerebellum, anastomose with the branches of the inferior cerebellar arteries. Several branches are given to the pineal gland, the valve of Vieussens, and the velum interpositum.

The **posterior cerebral arteries**, the two terminal branches of the basilar, are larger than the preceding, from which they are separated near their origin by the third nerves. Passing outward, parallel to the superior cerebellar artery, and receiving the posterior communicating from the internal carotid, they wind round the crura cerebri, and pass to the under surface of the occipital lobes of the cerebrum, and break up into branches for the supply of the temporal and occipital lobes. The branches of the posterior cerebral artery are:

Postero-median ganglionic.	Three terminal. {	Anterior temporal.
Posterior choroid.		Posterior temporal.
Postero-lateral ganglionic.		Occipital.

The *postero-median ganglionic branches* (Fig. 296) are a group of small arteries which arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated space, and supply the internal surfaces of the optic thalami and the walls of the third ventricle. The *posterior choroid* enters the interior of the brain beneath the splenium of the corpus callosum, and supplies the velum interpositum and the choroid plexus. The *postero-lateral ganglionic branches* are a group of small arteries which arise from the posterior cerebral artery, after it has turned round the crus cerebri; they supply a considerable portion of the optic thalamus. The *terminal branches* are distributed as follows: the first (*anterior temporal*) to the uncinatus gyrus; the second (*posterior temporal*) to the external occipital and the third temporal convolutions; and the third (*occipital*) to the inner and outer surfaces of the occipital lobe.

Circle of Willis.—The remarkable anastomosis which exists between the branches of the internal carotid and vertebral arteries at the base of the brain constitutes the *circle of Willis*. It is formed, in front, by the anterior cerebral arteries, branches of the internal carotid, which are connected together by the anterior communicating; behind, by the two posterior cerebrals, branches of the basilar, which are connected on each side with the internal carotid by the posterior communicating arteries (Fig. 291). It is by this anastomosis that the cerebral circulation is equalized, and provision made for effectually carrying it on if one or more of the branches are obliterated. The parts of the brain included within this arterial circle are—the lamina cinerea, the commissure of the optic nerves, the infundibulum, the tuber cinereum, the corpora albicantia, and the posterior perforated space.

The **Thyroid Axis** (Fig. 283) is a short thick trunk which arises from the fore part of the first portion of the subclavian artery, close to the inner border of the *Scalenus anticus* muscle, and divides, almost immediately after its origin, into three branches—the *inferior thyroid*, *suprascapular*, and *transversalis colli*.

The **Inferior thyroid artery** passes upward, in front of the vertebral artery and *Longus colli* muscle; then turns inward behind the sheath of the common carotid artery and internal jugular vein, and also behind the sympathetic nerve, the middle cervical ganglion resting upon the vessel, and, reaching the lower border of the lateral lobe of the thyroid gland, it divides into two branches, which supply the posterior and under part of the organ, and anastomose in its substance with the superior thyroid and with the corresponding artery of the opposite side. The recurrent laryngeal nerve passes upward, generally behind but occasionally in front of the artery. Its branches are: the

Inferior Laryngeal.
Tracheal.

Œsophageal.
Ascending Cervical.

Muscular.

The **inferior laryngeal branch** ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the branch from the opposite side and with the laryngeal branch from the superior thyroid artery.

The **tracheal branches** are distributed upon the trachea, anastomosing below with the bronchial arteries.

The **œsophageal branches** are distributed to the œsophagus, and anastomose with the œsophageal branches of the aorta.

The **ascending cervical** is a small branch which arises from the inferior thyroid just where that vessel is passing behind the common carotid artery, and runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the *Scalenus anticus* and *Rectus capitis anticus major*. It gives branches to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches into the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to

the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries.

The muscular branches supply the depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx.

Surgical Anatomy.—This artery has been tied, in conjunction with the superior thyroid, in cases of bronchocele. An incision is made along the anterior border of the Sterno-mastoid down to the clavicle. After the deep fascia has been divided, the Sterno-mastoid and carotid vessels are drawn outward and the carotid (Chassaignac's) tubercle sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side of the trachea and œsophagus on the inner side. In passing the ligature great care must be exercised to avoid including the recurrent laryngeal nerve, which is occasionally found crossing in front of the vessel.

The **Suprascapular artery (transversalis humeri)**, smaller than the transversalis colli, passes obliquely from within outward, across the root of the neck. It at first passes downward and outward across the Scalenus anticus and phrenic nerve, being covered by the Sterno-mastoid; it then crosses the subclavian artery and the cords of the brachial plexus, and runs outward, behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omc-hyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula, which separates it from the suprascapular nerve, to the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it supplies branches. It then passes downward

FIG. 300.—The scapular and circumflex arteries.

behind the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsalis scapulæ and posterior scapular arteries. Besides distributing branches to the Sterno-mastoid, Subclavius, and neighboring muscles, it gives off a *supra-sternal branch*, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and a *supra-acromial branch*, which, piercing the Trapezius muscle, supplies the skin over the acromion, anastomosing with the acromial thoracic artery. As the artery passes over the transverse ligament of the scapula, a branch descends into the subscapular fossa, ramifies beneath that muscle, and anastomoses with the posterior and subscapular arteries. It also sends branches to the acromio-clavicular and shoulder joints, and a nutrient artery to the clavicle.

The **Transversalis Colli** passes transversely outward, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the *superficial cervical* and the *posterior scap-*

ular. In its passage across the neck it crosses in front of the phrenic nerve, Scalenus muscles, and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sterno-mastoid, Omo-hyoid, and Trapezius muscles.

FIG. 301. — The internal mammary artery and its branches.

The **superficial cervical** ascends beneath the anterior margin of the Trapezius, distributing branches to it and to the neighboring muscles and glands in the neck, and anastomoses with the superficial branch of the arteria princeps cervicis.

The **posterior scapular** passes beneath the Levator anguli scapulæ to the superior angle of the scapula, and then descends along the posterior border of that bone as far as the inferior angle. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries, and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The *superficial cervical* frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.

The **Internal mammary** (Fig. 301) arises from the under surface of the first portion of the subclavian artery, opposite the thyroid axis. It passes downward and inward behind the costal cartilage of the first rib to the inner surface of the anterior wall of the chest, resting against the costal cartilages about half an inch from the margin of the sternum; and, at the interval between the sixth and seventh cartilages, divides into two branches, the *musculo-phrenic* and *superior epigastric*.

Relations.—At its origin it is covered by the internal jugular and subclavian veins, and as it enters the thorax is crossed from without inward by the phrenic nerve, and then passes forward close to the outer side of the innominate vein. In the upper part of the thorax it lies behind the costal cartilages and Internal intercostal muscles, and is crossed by the terminations of the upper six intercostal nerves. At first it lies upon the pleura, but at the lower part of the thorax the Triangularis sterni separates the artery from this membrane. It has two *venæ comites*; these unite into a single vein, which joins the innominate vein of its own side.

The branches of the internal mammary are—

Comes Nervi Phrenici (Superior Phrenic).	Anterior Intercostal.
Mediastinal.	Perforating.
Pericardiac.	Musculo-phrenic.
Sternal.	Superior Epigastric.

The **comes nervi phrenici** (*superior phrenic*), is a long slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm, to which it is distributed, anastomosing with the other phrenic arteries from the internal mammary and abdominal aorta.

The **mediastinal branches** are small vessels which are distributed to the areolar tissue and lymphatic glands in the anterior mediastinum and the remains of the thymus gland.

The **pericardiac branches** supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculo-phrenic artery.

The **sternal branches** are distributed to the Triangularis sterni and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura, which has been named by Turner the *subpleural mediastinal plexus*.

The **anterior intercostal arteries** supply the five or six upper intercostal spaces. The branch corresponding to each space soon divides into two, or the two branches may come off separately from the parent trunk. The small vessels pass outward in the intercostal spaces, one lying near the lower margin of the rib above, and the other near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles, and, by branches which perforate the External intercostal muscle, the Pectoral muscles and the mammary gland.

The **perforating arteries** correspond to the five or six upper intercostal spaces. They arise from the internal mammary, pass forward through the intercostal spaces, and, curving outward, supply the Pectoralis major and the integument.

Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland. In females, during lactation, these branches are of large size.

The **musculo-phrenic artery** is directed obliquely downward and outward, behind the cartilages of the false ribs, perforating the Diaphragm at the eighth or ninth rib, and terminating, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to each of the intercostal spaces across which it passes; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculo-phrenic also gives branches to the lower part of the pericardium, and others which run backward to the Diaphragm and downward to the abdominal muscles.

The **superior epigastric** continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some vessels perforate the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch, which passes inward upon the side of the ensiform appendix, anastomoses in front of that cartilage with the artery of the opposite side. It also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Surgical Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the chest-wall. It is most easily reached by a transverse incision in the second intercostal space.

The **Superior Intercostal** (Fig. 289) arises from the upper and back part of the subclavian artery, behind the Anterior scalenus muscle on the right side, and to the inner side of that muscle on the left side. Passing backward, it gives off the *deep cervical branch*, and then descends behind the pleura in front of the necks of the first two ribs, and inosculates with the first aortic intercostal. As it crosses the neck of the first rib it lies to the inner side of the anterior division of the first dorsal nerve and to the outer side of the first thoracic ganglion of the sympathetic. In the first intercostal space it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the highest aortic intercostal. Each intercostal gives off a branch to the posterior spinal muscles, and a small one which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The *deep cervical branch* (*profunda cervicis*) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery; occasionally it arises as a separate branch from the subclavian artery. Passing backward, above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis colli muscles, as high as the axis, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital, and with branches which pass outward from the vertebral. It gives off a special branch which enters the spinal canal through the intervertebral foramen between the seventh cervical and first dorsal vertebrae.

SURGICAL ANATOMY OF THE AXILLA.

The **Axilla** is a pyramidal space, situated between the upper and lateral part of the chest and the inner side of the arm.

Boundaries.—Its *apex*, which is directed upward toward the root of the neck, corresponds to the interval between the first rib, the upper edge of the scapula,

and the clavicle, through which the axillary vessels and nerves pass. The *base*, directed downward, is formed by the integument and a thick layer of fascia, the *axillary fascia*, extending between the lower border of the Pectoralis major in front and the lower border of the Latissimus dorsi behind; it is broad internally at the chest, but narrow and pointed externally at the arm. The *anterior boundary* is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part. The space between the inner border of the Pectoralis minor and the clavicle is occupied by the costo-coracoid membrane. The *posterior boundary*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *inner side* are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the *outer side*, where the anterior and posterior boundaries converge, the space is narrow, and bounded by the humerus, the Coraco-brachialis and Biceps muscles.

Contents.—This space contains the axillary vessels and brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymphatic glands, all connected together by a quantity of fat and loose areolar tissue.

Their Position.—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axillary space, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axillary space, in contact with the Pectoral muscles, are the thoracic branches of the axillary artery, and along the anterior margin

FIG. 302.—The axillary artery and its branches.

are the thoracic branches of the axillary artery, and along the lower margin of the Pectoralis minor the long thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the outer border of this muscle is

the dorsalis scapulæ artery and veins; and, close to the neck of the humerus, the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation—viz. the posterior thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercosto-humeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue and a large number of small arteries and veins, all of which are, however, of inconsiderable size, and numerous lymphatic glands, the position and arrangement of which are described on a subsequent page.

Surgical Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease: it contains numerous lymphatic glands which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or inflammatory exudation, and it may be the seat of rapidly-growing tumors. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous abscesses and boils, and of eruptions due to irritation.

In suppuration in the axilla the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on page 379, the costo-coracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the axillary fascia at the anterior fold of the axilla. This is known as the clavi-pectoral fascia. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorals or below the Pectoralis minor: in the former case, it would point either at the anterior border of the axillary fold or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the skin is prevented by the axillary fascia; its progress backward, by the Serratus magnus; forward, by the clavi-pectoral fascia; inward, by the wall of the thorax; and outward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an axillary abscess the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps after an incision has been made through the skin and fascia in the manner directed by the late Mr. Hilton.

The student should attentively consider the relation of the vessels and nerves in the several parts of the axilla, for it is the almost universal plan, in the present day, to remove the glands from the axilla in operating for cancer of the breast. In performing such an operation it will be necessary to proceed with much caution in the direction of the outer wall and apex of the space, as here the axillary vessels will be in danger of being wounded. Toward the posterior wall it will be necessary to avoid the subscapular, dorsalis scapulæ, and posterior circumflex vessels. Along the anterior wall it will be necessary to avoid the thoracic branches. In clearing out the axilla the axillary vein should be first defined and cleared by the fingers and an elevator up to the apex of the axilla, the Pectoralis major being pulled up by an assistant with a retractor. When the apex of the space is reached, all fat and glands must be carefully removed and the whole axilla cleared by separating the tissues along the inner and posterior walls, so that when the proceeding is completed, the axilla is cleared of all its contents except the main vessels and nerves.

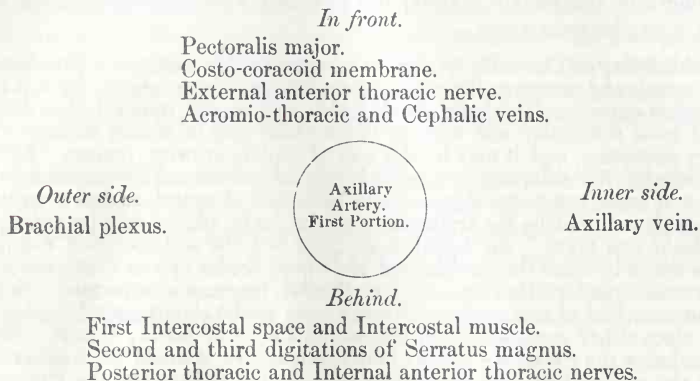

THE AXILLARY ARTERY.

The **Axillary Artery**, the continuation of the subclavian, commences at the outer border of the first rib, and terminates at the lower border of the tendon of the Teres major muscle, where it takes the name of brachial. Its direction varies with the position of the limb: when the arm lies by the side of the chest, the vessel forms a gentle curve, the convexity being upward and outward; when it is directed at right angles with the trunk, the vessel is nearly straight; and when it is elevated still higher, the artery describes a curve the concavity of which is directed upward. At its commencement the artery is very deeply situated, but near its termination is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three

portions, the first portion being that above the Pectoralis minor; the second portion, behind; and the third below, that muscle.

The first portion of the axillary artery is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costo-coracoid membrane, the external anterior thoracic nerve, and the acromio-thoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the second and a portion of the third digitations of the Serratus magnus, and the posterior thoracic and internal anterior thoracic nerves; on its *outer side*, with the brachial plexus, from which it is separated by a little cellular interval; on its *inner* or thoracic side, with the axillary vein, which overlaps the artery.

RELATIONS OF THE FIRST PORTION OF THE AXILLARY ARTERY.

The second portion of the axillary artery lies behind the Pectoralis minor. It is covered, *in front*, by the Pectoralis major and minor muscles; *behind*, it is separated from the Subscapularis by a cellular interval; on the *inner side* is the axillary vein, separated from the artery by the inner cord of the plexus and the internal anterior thoracic nerve. The brachial plexus of nerves surrounds the artery on three sides, and separates it from direct contact with the vein and adjacent muscles.

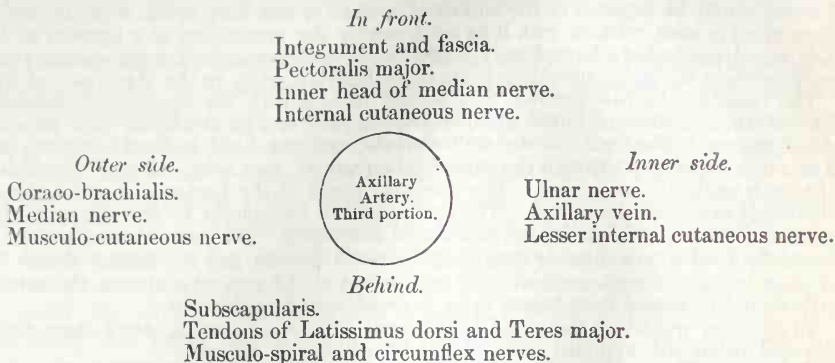

RELATIONS OF THE SECOND PORTION OF THE AXILLARY ARTERY.

The third portion of the axillary artery lies below the Pectoralis minor. It is in relation, *in front*, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below, where it is crossed by the inner head of the median nerve; *behind*, with the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major; on its *outer side*, with the Coraco-brachialis; on its *inner* or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course: on the *outer side* is the median nerve, and the musculo-cutaneous for a short distance; on the *inner side*, the ulnar (between the vein and artery) and lesser internal cutaneous nerves (to the inner side of the vein); *in front*, is the

internal cutaneous nerve, and *behind*, the musculo-spiral and circumflex, the latter extending only to the lower border of the Subscapularis muscle.

RELATIONS OF THE THIRD PORTION OF THE AXILLARY ARTERY.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm or a large muscular trunk. In the first set of cases this artery is most frequently the radial (1 in 33), sometimes the ulnar (1 in 72), and, very rarely, the interosseous (1 in 506). In the second set of cases the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes only one of the circumflex, or one of the profunda arteries, arose from the trunk. In these cases the brachial plexus surrounded the trunk of the branches and not the main vessel.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coraco-brachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coraco-brachialis.

Surgical Anatomy.—The student, having carefully examined the relations of the axillary artery in its various parts, should now consider in what situation compression of this vessel may be most easily effected, and the best position for the application of a ligature to it when necessary.

Compression of the vessel may be required in the removal of tumors or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outward against the humerus the circulation may be effectually arrested.

The axillary artery is perhaps more frequently lacerated than any other artery in the body, with the exception of the popliteal, by violent movements of the upper extremity, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint. This lesion is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having become fixed to the capsule of the joint. Aneurism of the axillary artery is of frequent occurrence, a large percentage of the cases being traumatic in their origin, due to the violence to which it is exposed in the varied, extensive, and often violent movement of the limb.

The **application of a ligature to the axillary artery** may be required in cases of aneurism of the upper part of the brachial or as a distal operation for aneurism of the sub-clavian; and there are only two situations in which it can be secured—viz. in the first and in the third parts of its course; for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nervous trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the **third part** of its course the operation is most simple, and may be performed in the following manner: The patient being placed on a bed and the arm separated from the side, with the hand supinated, an incision is made through the integument forming the floor of the axilla about two inches in length, a little nearer to the anterior than the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed round the artery from the ulnar to the radial side.

This portion of the artery is occasionally crossed by a muscular slip, the *axillary arch*, derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscular fasciculus was spoken of in the description of the muscles. It may easily be recognized by the transverse direction of its fibres.

The first portion of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that in this situation it would be necessary to divide a thick muscle, and, after incising the costo-coracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the vessel particularly hazardous. Under such circumstances it is an easier, and at the same time more advisable, operation to tie the subclavian artery in the third part of its course.

The vessel can be best secured by a curved incision with the convexity downward from a point half an inch external to the Sterno-clavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and this incision carried through the superficial structures, care being taken of the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downward. The costo-coracoid membrane is to be carefully divided on a director close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

In a case of wound of the vessel the general practice of cutting down upon, and tying it above and below the wounded point should be adopted in all cases.

Collateral Circulation after Ligature of the Axillary Artery.—If the artery be tied above the origin of the acromial thoracic, the collateral circulation will be carried on by the same branches as after the ligature of the subclavian; if at a lower point, between the acromial thoracic and subscapular arteries, the latter vessel, by its free anastomoses with the other scapular arteries, branches of the subclavian, will become the chief agent in carrying on the circulation, to which the long thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature be below the origin of the subscapular artery, it will most probably also be below the origins of the two circumflex arteries. The chief agents in restoring the circulation will then be the subscapular and the two circumflex arteries anastomosing with the superior profunda from the brachial, which will be afterward referred to as performing the same office after ligation of the brachial. The cases in which the operation has been performed are few in number, and no published account of dissections of the collateral circulation appears to exist.

BRANCHES OF THE AXILLARY ARTERY.

The branches of the axillary artery are—

<i>From first part</i>	{ Superior Thoracic.	<i>From second part</i>	{ Long Thoracic.
	{ Acromial Thoracic.		{ Alar Thoracic.
<i>From third part</i>	{ Subscapular.		
	{ Posterior Circumflex.		
	{ Anterior Circumflex.		

The **superior thoracic** is a small artery which arises from the axillary separately or by a common trunk with the acromial thoracic. Running forward and inward along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the chest. It supplies these muscles and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **acromial thoracic** is a short trunk which arises from the fore part of the axillary artery, its origin being generally overlapped by the upper edge of the Pectoralis minor. Projecting forward to the upper border of the Pectoralis minor, it divides into three sets of branches—*thoracic*, *acromial*, and *descending*. The *thoracic branches*, two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary. The *acromial branches* are directed outward toward the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries. The *descending* or *humeral branch* passes in the space between the Pectoralis major and Deltoid in the same groove as the cephalic vein, and supplies both muscles. The artery also gives off a very small branch, the *clavicular*, which passes upward to the Subclavius muscle.

The **long thoracic** passes downward and inward along the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus magnus, the

Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary and intercostal arteries.

The **alar thoracic** is a small branch which supplies the glands and areolar tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **subscapular**, the largest branch of the axillary artery, arises opposite the lower border of the Subscapularis muscle, and passes downward and backward along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular, a branch of the transversalis colli, from the thyroid axis of the subclavian. About an inch and a half from its origin it gives off a large branch, the *dorsalis scapulæ*, and terminates by supplying branches to the muscles in the neighborhood.

The *dorsalis scapulæ* is given off from the subscapular about an inch and a half from its origin, and is generally larger than the continuation of the vessel. It curves round the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (Fig. 300), and enters the infraspinous fossa by passing under cover of the Teres minor, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two sets of branches: one enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

The **circumflex arteries** wind round the neck of the humerus. The *posterior circumflex* (Fig. 300), the larger of the two, arises from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backward with the circumflex veins and nerve through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds round the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The *anterior circumflex* (Figs. 300, 302), considerably smaller than the preceding, arises nearly opposite that vessel from the outer side of the axillary artery. It passes horizontally outward beneath the Coraco-brachialis and short head of the Biceps, lying upon the fore part of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upward along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outward beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

THE BRACHIAL ARTERY (Fig. 303).

The **Brachial Artery** commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the *radial* and *ulnar arteries*. At first the brachial artery lies internal to the humerus; but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two condyles.

Relations.—This artery is superficial throughout its entire extent, being covered, *in front*, by the integument, the superficial and deep fasciæ; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle; *behind*, it is separated from the long head of the Triceps by the musculo-spiral nerve and superior profunda artery. It then lies upon the

inner head of the Triceps, next upon the insertion of the Coraco-brachialis, and lastly on the Brachialis anticus; by its *outer side*, it is in relation with the commencement of the median nerve and the Coraco-brachialis and Biceps muscles, which overlap the artery to a considerable extent; by its *inner side*, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. It is accompanied by two venæ comites, which lie in close contact with the artery, being connected together at intervals by short transverse communicating branches.

SURGICAL ANATOMY OF THE BEND OF THE ELBOW.

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the base of which is directed upward, and may be represented by a line connecting the two condyles of the humerus; the sides are bounded, externally, by the inner edge of the Supinator longus; internally, by the outer margin of the Pronator radii teres; its floor is formed by the Brachialis anticus and Supinator brevis. This space contains the brachial artery with its accompanying veins, the radial and ulnar arteries, the median and musculo-spiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. *Behind*, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid origin of the Pronator radii teres. The tendon of the Biceps lies to the outer side of the space, and the musculo-spiral nerve still more externally, situated upon the Supinator brevis and partly concealed by the Supinator longus.

Peculiarities of the Brachial Artery as regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps and descend toward the inner condyle of the humerus, where it usually curves round a prominence of bone, the *supra-condylar process*, from which a fibrous arch is usually thrown over the artery; it then inclines outward, beneath or through the substance of the Pronator radii teres muscle, to the bend of the elbow. The variation bears considerable analogy to the normal condition of the artery in some of the carnivora: it has been referred to in the description of the humerus (page 146).

As regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The point of bifurcation may be above or below the usual point, the former condition being by far the more frequent. Out of 481 examinations recorded by Mr. Quain, some made on the right and some on the left side of the body, in 386 the artery bifurcated in its normal position. In one case only was the place of division lower than usual, being two or three inches below the elbow-joint. "In 94 cases out of 481, or about 1 in 5 $\frac{1}{2}$, there were two arteries instead of one in some part or in the whole of the arm."

There appears, however, to be no correspondence between the arteries of the two arms with respect to their irregular division; for in 61 bodies it occurred on one side only in 43; on both sides, in different positions, in 13; on both sides, in the same position, in 5.

The point of bifurcation takes place at different parts of the arm, being most frequent in the upper part, less so in the lower part, and least so in the middle, the most usual point for the application of a ligature; under any of these circumstances two large arteries would be found in the arm instead of one. The most frequent (in three out of four) of these peculiarities is the high division of the radial. That artery often arises from the inner side of the brachial, and runs parallel with the main trunk to the elbow, where it crosses it, lying beneath the fascia; or it may perforate the fascia and pass over the artery immediately beneath the integument.

The ulnar sometimes arises from the brachial high up, and accompanies that vessel to the lower part of the arm, and descends toward the inner condyle. In the forearm it generally lies beneath the deep fascia, superficial to the flexor muscles; occasionally between the integument and deep fascia, and very rarely beneath the flexor muscles.

The interosseous artery sometimes arises from the upper part of the brachial or axillary; as it passes down the arm it lies behind the main trunk, and at the bend of the elbow regains its usual position.

In some cases of high division of the radial the remaining trunk (ulnar interosseous) occasionally passes, together with the median nerve, along the inner margin of the arm to the inner condyle, and then passing from within outward, beneath or through the Pronator radii teres, regains its usual position at the bend of the elbow.

Occasionally the two arteries representing the brachial are connected at the bend of the elbow by a short transverse branch, and are even sometimes reunited.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

Varieties in Muscular Relations.¹—The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coraco-brachialis, Biceps, Brachialis anticus, and Pronator radii teres muscles.

Surface Marking.—The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the insertion of the Teres major muscle to the point midway between the condyles of the humerus.

Surgical Anatomy.—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward; and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coraco-brachialis on the inner flat side of the humerus.

¹ See Struther's *Anatomical and Physiological Observations*.

FIG. 303.—The brachial artery.

The application of a ligature to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coraco-brachialis and Biceps, the known course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscular fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner: The patient being placed supine upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coraco-brachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venæ comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed round the artery from the inner to the outer side.

If two arteries are present in the arm in consequence of a high division, they are usually placed side by side: and if they are exposed in an operation, the surgeon should endeavor to ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hæmorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk: a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest in a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the median basilic is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied below the origin of the profunda arteries, the circulation is maintained by the branches of the profundæ, anastomosing with the recurrent radial, ulnar, and interosseous arteries. In two cases described by Mr. South,¹ in which the brachial artery had been tied some time previously, in one "a long portion of the artery had been obliterated, and sets of vessels are descending on either side from above the obliteration, to be received into others which ascend in a similar manner from below it. In the other the obliteration is less extensive, and a single curved artery about as big as a crow-quill passes from the upper to the lower open part of the artery."

The branches of the brachial artery are—the

Superior Profunda.
Nutrient.

Inferior Profunda.
Anastomotica Magna.

Muscular.

¹ Chelius's *Surgery*, vol. ii. p. 254. See also White's engraving, referred to by Mr. South, of the anastomosing branches after ligature of the brachial, in White's *Cases in Surgery*. Porta also gives a case (with drawings) of the circulation after ligature of both brachial and radial (*Alterazioni Patologiche delle Arterie*).

The **superior profunda** arises from the inner and back part of the brachial, just below the lower border of the *Teres major*, and passes backward to the interval between the outer and inner heads of the *Triceps* muscle, accompanied by the musculo-spiral nerve; it winds around the back part of the shaft of the humerus in the spiral groove, between the outer head of the *Triceps* and the bone, to the outer side of the humerus, where it reaches the external intermuscular septum and divides into two terminal branches. One of these pierces the external intermuscular septum, and descends, in company with the musculo-spiral nerve, to the space between the *Brachialis anticus* and *Supinator longus*, where it anastomoses with the recurrent branch of the radial artery; while the other, much the larger of the two, descends along the back of the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the *anastomotica magna*, and inferior profunda (Fig. 306). The superior profunda supplies the *Triceps* muscle and gives off a nutrient artery which enters the bone at the upper end of the musculo-spiral groove. Near its commencement it sends off a branch which passes upward between the external and long heads of the *Triceps* muscle to anastomose with the posterior circumflex artery, and, while in the groove, a small branch which accompanies a branch of the musculo-spiral nerve through the substance of the *Triceps* muscle and ends in the *Anconeus* below the outer condyle of the humerus.

The **nutrient artery** of the shaft of the humerus arises from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the *Coraco-brachialis* muscle.

The **inferior profunda**, of small size, arises from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the *Triceps* muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and *anastomotica magna*. It sometimes supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The ***anastomotica magna*** arises from the brachial about two inches above the elbow-joint. It passes transversely inward upon the *Brachialis anticus*, and, piercing the internal intermuscular septum, winds round the back part of the humerus between the *Triceps* and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the *Brachialis anticus*, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the *Triceps*.

The **muscular** are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the *Coraco-brachialis*, *Biceps*, and *Brachialis anticus* muscles.

The Anastomosis around the Elbow-joint (Fig. 306).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* and *behind* the internal and external condyles. The branches anastomosing *in front* of the internal condyle are the *anastomotica magna*, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those *behind* the internal condyle are the *anastomotica magna*, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing *in front* of the external condyle are the radial recurrent and the anterior terminal branch of the superior profunda. Those *behind* the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the *anastomotica magna*, the interosseous recurrent, and the posterior terminal branch of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the *anastomotica magna* and posterior ulnar recurrent (Fig. 306).

From this description it will be observed that the *anastomotica magna* is the vessel most engaged, the only part of the anastomosis in which it is not employed being that *in front* of the external condyle.

Radial Artery (Fig. 304).

The **Radial Artery** appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backward, round the outer side of the carpus, beneath the extensor tendons of the thumb, to the upper end of the space between the metacarpal bones of the thumb and index finger, and, finally, passes forward, between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the deep palmar arch. At its termination it inosculates with the deep branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz., in the forearm, at the back of the wrist, and in the hand.

Relations.—*In the forearm* this vessel extends from opposite the neck of the radius to the fore part of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Supinator longus muscle; throughout the rest of its course it is superficial, being covered by the integument, the superficial and deep fasciæ. In its course downward it lies upon the tendon of the Biceps, the Supinator brevis, the Pronator radii teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Supinator longus and the Pronator radii teres; in its lower two-thirds, between the tendons of the Supinator longus and the Flexor carpi radialis. The radial nerve lies close to the outer side of the artery in the middle third of its course, and some filaments of the musculo-cutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds round the wrist. The vessel is accompanied by venæ comites throughout its whole course.

PLAN OF THE RELATIONS OF THE RADIAL ARTERY IN THE FOREARM.

At the wrist, as it winds round the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculo-cutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it inosculates with the communicating branch from the ulnar artery, forming the deep palmar arch. It lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor minimi digiti. Alongside of it is the deep branch of the ulnar nerve, but running in the opposite direction; that is to say, from within outward.

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed on the surface of the Supinator longus, instead of under its inner border; and in turning round the wrist it has been seen lying over, instead of beneath, the extensor tendons of the thumb.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the fore part of the styloid process of the radius.

Surgical Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and such-like accidents. The injury is often followed by a traumatic aneurism, for which the old operation of laying open the sac and securing the vessel above and below is required.

The operation of tying the radial artery is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Supinator longus muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Supinator longus drawn a little outward, the artery will be exposed. The venæ comites should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Supinator longus. In this situation the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Supinator longus and Flexor carpi radialis muscles.

The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

<i>In the Forearm.</i>	{	Radial Recurrent.	<i>Wrist.</i>	{	Posterior Carpal.
		Muscular.			Metacarpal.
		Anterior Carpal.			Dorsales Pollicis.
		Superficialis Volæ.			Dorsalis Indicis.
<i>Hand.</i>	{				Princeps Pollicis.
					Radialis Indicis.
					Perforating.
					Palmar Interosseous.
					Palmar Recurrent.

The **radial recurrent** is given off immediately below the elbow. It ascends between the branches of the musculo-spiral nerve lying on the Supinator brevis, and then between the Supinator longus and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with the terminal branches of the superior profunda.

The **muscular branches** are distributed to the muscles on the radial side of the forearm.

The **anterior carpal** is a small vessel which arises from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, *anterior carpal arch*, is formed in front of the wrist; it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep palmar arch below, and gives off branches which descend to supply the articulations of the wrist and carpus.

The **superficialis volæ** arises from the radial artery, just where this vessel is about to wind round the wrist. Running forward, it passes between, occasionally over, the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size: usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **posterior carpal** is a small vessel which arises from the radial artery beneath the extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the *posterior carpal arch*, which is joined by the termination of the anterior interosseous artery. From this arch are given off descending branches, the *dorsal interosseous arteries* for the third and fourth interosseous spaces, which run forward on the Third and Fourth dorsal interossei muscles, and divide into dorsal digital branches which supply the adjacent sides of the middle, ring, and little fingers respectively, communicating with the digital arteries of the superficial palmar arch. At their origin they anastomose with the perforating branches from the deep palmar arch.

The **metacarpal (first dorsal interosseous branch)** arises beneath the extensor tendons of the thumb, sometimes with the posterior carpal

FIG. 304.—The radial and ulnar arteries.

artery; running forward on the Second dorsal interosseous muscle, it communicates, behind, with the corresponding perforating branch of the deep palmar arch; and

in front it divides into two *dorsal digital branches*, which supply the adjoining sides of the index and middle fingers, inosculating with the digital branch of the superficial palmar arch.

The *dorsales pollicis* are two vessels which run along the sides of the dorsal aspect of the thumb. They arise separately, or occasionally by a common trunk, near the base of the first metacarpal bone.

The *dorsalis indicis*, also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The *princeps pollicis* arises from the radial just as it turns inward to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it divides into two branches, which run along the sides of the palmar aspect of the thumb, and form an arch on the palmar surface of the last phalanx, from which branches are distributed to the integument and pulp of the thumb.

The *radialis indicis* arises close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the *princeps pollicis*, and gives a communicating branch to the superficial palmar arch.

The *perforating arteries*, three in number, pass backward from the deep palmar arch between the heads of the last three Dorsal interossei muscles, to inosculate with the dorsal interosseous arteries.

The *palmar interosseous*, three or four in number, arise from the convexity of the deep palmar arch; they run forward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The *palmar recurrent branches* arise from the concavity of the deep palmar arch. They pass upward in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

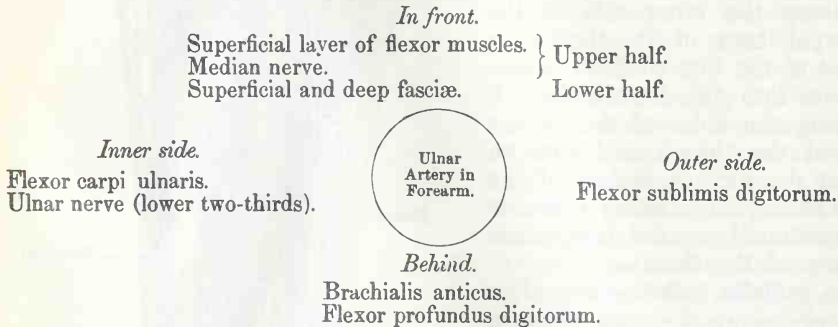

FIG. 305.—Ulnar and radial arteries. Deep view.

Ulnar Artery (Fig. 305).

The **Ulnar Artery**, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and crosses obliquely the inner side of the forearm, to the commencement of its lower half; it then runs along its ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches which enter into the formation of the superficial and deep palmar arches.

Relations in the Forearm.—In its *upper half* it is deeply seated, being covered by all the superficial Flexor muscles, excepting the Flexor carpi ulnaris; the median nerve is in relation with the inner side of the artery for about an inch and then crosses the vessel, being separated from it by the deep head of the Pronator radii teres; it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the *lower half* of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

PLAN OF RELATIONS OF THE ULNAR ARTERY IN THE FOREARM.

At the wrist (Fig. 304) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone. The ulnar nerve lies at the inner side, and somewhat behind the artery; here the nerve and artery are crossed by a band of fibres, which extends from the pisiform bone to the anterior annular ligament.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source of origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. First, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. Secondly, draw a line from the centre of the hollow in front of the elbow-joint to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Surgical Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other flexor muscles

is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside. Some little distance below the nerve the artery will be found accompanied by its venæ comites, and may be ligatured by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris: the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venæ comites, the ulnar nerve lying on its inner side. The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

The branches of the ulnar artery may be arranged in the following groups:

	{ Anterior Ulnar Recurrent. { Posterior Ulnar Recurrent.	
<i>Forearm.</i>	{ Interosseous { Anterior Interosseous. { Posterior Interosseous.	
	{ Muscular.	
<i>Wrist.</i>	{ Anterior Carpal. { Posterior Carpal.	
<i>Hand.</i>	{ Deep Palmar or Communicating. { Superficial Palmar Arch.	

The **anterior ulnar recurrent** (Fig. 305) arises immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator radii teres, supplies twigs to those muscles, and, in front of the inner condyle, anastomoses with the anastomotica magna and inferior profunda.

The **posterior ulnar recurrent** is much larger, and arises somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries (Fig. 306).

The **interosseous artery** (Fig. 305) is a short trunk about half an inch in length, and of considerable size, which arises immediately below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the *anterior* and *posterior interosseous*.

The **anterior interosseous** passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation muscular branches and the nutrient arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch descends beneath the muscle to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, reaches the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 306). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives off a long, slender branch, the *median artery*, which accompanies the median nerve and gives offsets to its substance. This artery is sometimes much enlarged, and accompanies the nerve into the palm of the hand.

The **posterior interosseous artery** passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator brevis and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery. Then, continuing its course over the head of the ulna, it

joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the *interosseous recurrent branch*.

The *interosseous recurrent artery* is a large vessel which ascends to the interval

between the external condyle and olecranon, on or through the fibres of the *Supinator brevis*, but beneath the *Anconeus*, anastomosing with a branch from the *superior profunda*, and with the *posterior ulnar recurrent* and *anastomotica magna*.

The *muscular branches* are distributed to the muscles along the ulnar side of the forearm.

The *anterior carpal* is a small vessel which crosses the front of the carpus beneath the tendons of the *Flexor profundus*, and inosculates with a corresponding branch of the *radial artery*.

The *posterior carpal* arises immediately above the pisiform bone, and winds backward beneath the tendon of the *Flexor carpi ulnaris*: it passes across the dorsal surface of the carpus beneath the extensor tendons, anastomosing with a corresponding branch of the *radial artery*, and forming the *posterior carpal arch*. Immediately after its origin it gives off a small branch which runs along the ulnar side of the metacarpal bone of the little finger, forming one of the *metacarpal arteries*, and supplies the ulnar side of the dorsal surface of the little finger.

The branch to the *deep palmar arch* (*deep or communicating branch*) (Fig. 305) passes deeply inward between the *Abductor minimi digiti* and *Flexor brevis minimi digiti*, near their origins; it anastomoses with the termination of the *radial artery*, completing the *deep palmar arch*.

The continuation of the trunk of the *ulnar artery* in the hand forms the greater part of the *superficial palmar arch*.

FIG. 306.—Arteries of the back of the forearm and hand.

The Superficial Palmar Arch (Fig. 304).

The **Superficial Palmar Arch** is formed by the *ulnar artery* in the hand, and is completed on the outer side by this vessel anastomosing with a branch from the *radialis indicis*, though sometimes the arch is completed by the *ulnar* anastomosing

with the superficialis volæ or princeps pollicis of the radial artery. The arch passes across the palm, describing a curve, with its convexity forward, to the space between the ball of the thumb and the index finger, where the above-mentioned anastomosis takes place.

Relations.—The superficial palmar arch is covered by the skin, the Palmaris brevis, and the palmar fascia. It lies upon the annular ligament, the Flexor brevis of the little finger, the tendons of the superficial flexor of the fingers, and the divisions of the median and ulnar nerves.

PLAN OF THE RELATIONS OF THE SUPERFICIAL PALMAR ARCH.

Superficial flexor tendons.
Divisions of median and ulnar nerves.

BRANCHES OF THE SUPERFICIAL PALMAR ARCH.

Digital.

The **digital branches** (Fig. 304), four in number, are given off from the convexity of the superficial palmar arch. They supply the ulnar side of the little finger and the adjoining sides of the little, ring, middle, and index fingers, the radial side of the index finger and thumb being supplied from the radial artery. The digital arteries at first lie superficial to the flexor tendons, but as they pass forward with the digital nerves to the clefts between the fingers they lie between them, and are there joined by the interosseous branches from the deep palmar arch. The digital arteries on the sides of the fingers lie beneath the digital nerves; and about the middle of the last phalanx the two branches for each finger form an arch, from the convexity of which branches pass to supply the pulp of the finger.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger.

The deep palmar arch is situated about half an inch nearer to the carpus.

Surgical Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the superficial arch is wounded it is generally possible, by enlarging the wound if necessary, to secure the vessel and tie it; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of Wells's artery clips may be applied and left on for twenty-four or forty-eight hours. Wounds of the deep arch are not so easily dealt with. It may be possible to secure the vessel by forcipressure forceps, which may be left on; or, failing this, the wound may be carefully plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligate one of the arteries of the forearm alone, and indeed simultaneous ligation of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hemorrhage, it is expedient to apply a ligature to the brachial artery.

ARTERIES OF THE TRUNK.

THE DESCENDING AORTA.

The **Descending Aorta** is divided into two portions, the *thoracic* and *abdominal*, in correspondence with the two great cavities of the trunk in which it is situated.

THE THORACIC AORTA.

The **Thoracic Aorta** commences at the lower border of the fourth dorsal vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the lower border of the last dorsal vertebra. At its commencement it is situated on the left side of the spine; it approaches the median line as it descends, and at its termination lies directly in front of the column. The direction of this vessel being influenced by the spine, upon which it rests, it describes a curve which is concave forward in the dorsal region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable. It is contained in the back part of the posterior mediastinum.

Relations.—It is in relation, *in front*, from above downward, with the root of the left lung, the pericardium, the œsophagus, and the Diaphragm: *behind*, with the vertebral column and the vena azygos minor; on the *right side*, with the vena azygos major and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying nerves, lies on the right side of the aorta *above*; but at the lower part of the thorax it gets in front of the aorta, and close to the Diaphragm is situated to its left side.

PLAN OF THE RELATIONS OF THE THORACIC AORTA.

The aorta is occasionally found to be obliterated at a particular spot—viz., at the junction of the arch with the thoracic aorta, just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the *Pathological Transactions*, vols. viii. and x. In the former (p. 162) Mr. Sydney Jones thus sums up the detailed description of the anastomosing vessels: "The principal communications by which the circulation was carried on, were—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comes nervi phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals." In the second case also (vol. x. p. 97) Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark that "the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis, while the supply to the lower extremities had passed through the internal mammary and epigastrics."

Surgical Anatomy.—The student should now consider the effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the spine, producing absorption of the bodies of the vertebrae, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone, or it may displace the œsophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the œsophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hæmorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and lastly, it may open into the posterior mediastinum.

BRANCHES OF THE THORACIC AORTA.

Pericardiac.

Æsophageal.

Bronchial.

Posterior Mediastinal.

Intercostal.

The **pericardiac** are a few small vessels, irregular in their origin, distributed to the pericardium.

The **bronchial arteries** are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing along the bronchial tube, supplying them, the cellular tissue of the lungs, the bronchial glands, and the œsophagus.

The **œsophageal arteries**, usually four or five in number, arise from the front of the aorta, and pass obliquely downward to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **posterior mediastinal arteries** are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.

The **Intercostal arteries** arise from the back of the aorta. They are usually nine in number on each side, the two superior intercostal spaces being supplied by the superior intercostal, a branch of the subclavian. The second space usually receives a considerable branch from the first aortic intercostal, which joins with the branch from the superior intercostal of the subclavian. The branch which runs along the lower border of the last rib is named the *subcostal artery*. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine: they pass outward, across the bodies of the vertebrae, to the intercostal spaces, being covered by the pleura, the œsophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left, passing outward, are crossed by the sympathetic; the upper two are also crossed by the superior intercostal vein, the lower by the azygos minor veins. In each intercostal space the artery passes outward, at first lying upon the External intercostal muscle, covered in front by the pleura and a thin fascia. It then passes between the two layers of Intercostal muscles, and, having ascended obliquely to the lower border of the rib above it, is continued forward in the groove on its lower border and anastomoses with the anterior intercostal branches of the internal mammary. The first aortic intercostal anastomoses with the superior intercostal, and the last three pass between the abdominal muscles, inosculating with the epigastric in front

and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the

FIG. 307.—The abdominal aorta and its branches.

abdominal wall, except the *subcostal*, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

Each intercostal artery gives off the following branches:

Posterior or dorsal branch.

Spinal.

Collateral intercostal.

The **posterior or dorsal branch** of each intercostal artery passes backward to the inner side of the anterior costo-transverse ligament, and divides into an external and internal branch, which are distributed to the muscles and integument of the back.

The **spinal branch**, which enters the spinal canal through the intervertebral foramen, is distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral.

The **collateral intercostal branch** comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary.

Surgical Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

THE ABDOMINAL AORTA (Fig. 307).

The **Abdominal Aorta** commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the last dorsal vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,¹ where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ, the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

Relations.—It is covered, *in front*, by the lesser omentum and stomach, behind which are the branches of the celiac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. *Behind*, it is separated from the lumbar vertebræ and intervening discs by the anterior common ligament and left lumbar veins. On the *right side* it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the *left side*, with the sympathetic nerve and left semilunar ganglion.

¹ Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right" (*System of Surgery*, edited by T. Holmes, 2d éd., vol. v., p. 652).

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—Aneurisms of the abdominal aorta near the cœliac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancing pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupart's ligament; hæmorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismal sac is connected with the front of the aorta near the cœliac axis, it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backward so as to affect the spine.

The abdominal aorta has been tied several times, and although none of the patients permanently recovered, still, as one of them lived as long as ten days, the possibility of the re-establishment of the circulation may be considered to be proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines toward the spine, the peritoneum again opened behind by scratching through the mesentery, and the vessel thus reached. Or either of the operations described below for securing the common iliac artery may, by extending the dissection a sufficient distance upward, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living subject the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly that it is very doubtful whether it ought ever to be performed.

The collateral circulation would be carried on by the anastomosis between the internal mammary and the deep epigastric; by the free communication between the superior and inferior mesenterics if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

The circulation through the abdominal aorta may be commanded, in thin persons, by firm pressure with the fingers. A tourniquet has been invented for this purpose which is sometimes used in amputation at the hip-joint and some other operations.

BRANCHES OF THE ABDOMINAL AORTA.

Phrenic.		Superior Mesenteric.	Ovarian in female.
Cœliac Axis.	{ Gastric.	Suprarenal.	Inferior Mesenteric.
	{ Hepatic.	Renal.	Lumbar.
	{ Splenic.	Spermatic in male.	Sacra Media.

The branches may be divided into two sets: 1. Those supplying the viscera.
2. Those distributed to the walls of the abdomen.

<i>Visceral Branches.</i>		Renal.
		Spermatic or Ovarian.

	{ Hepatic.	
	{ Splenic.	
Superior Mesenteric.		Phrenic.
Inferior Mesenteric.		Lumbar.
Suprarenal.		Sacra Media.

The Cœliac Axis (Fig. 308).

To expose this artery raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

The Cœliac Axis is a short thick trunk, about half an inch in length, which

FIG. 308.—The cœliac axis and its branches, the liver having been raised and the lesser omentum removed.

arises from the aorta, close to the margin of the opening in the Diaphragm, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the *gastric*, *hepatic*, and *splenic*, occasionally giving off one of the phrenic arteries.

Relations.—It is covered by the lesser omentum. On the *right side* it is in relation with the right semilunar ganglion and the lobus Spigelii; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.

The **Gastric or Coronary Artery**, the smallest of the three branches of the celiac axis, passes upward and to the left side, to the cardiac orifice of the stomach, distributing branches to the œsophagus which anastomose with the aortic œsophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery; it then passes from left to right, along the lesser curvature of the stomach to the pylorus, lying in its course between the layers of the lesser omentum, and giving branches to both surfaces of the organ: at its termination it anastomoses with the pyloric branch of the hepatic.

The **Hepatic Artery** in the adult is intermediate in size between the gastric and splenic; in the fœtus it is the largest of the three branches of the celiac axis. It is first directed forward and to the right, to the upper margin of the pyloric end

of the stomach, forming the lower boundary of the foramen of Winslow. It then passes upward between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portæ and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery and the vena portæ behind.

Its branches are—the

Pyloric.

Gastro-duodenalis

{ Gastro-epiploica Dextra.
Pancreatico-duodenalis Superior.

Cystic.

The pyloric branch arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from right to left along its lesser curvature,

supplying it with branches and inosculating with the gastric branches of the coronary artery.

The gastro-duodenalis (Fig. 309) is a short but large branch, which descends, near the pylorus, behind the first portion of the duodenum, and divides at the lower border of this viscus into two branches, the *gastro-epiploica dextra* and the *pancreatico-duodenalis superior*. Previous to its division, it gives off two or three small inferior pyloric branches to the pyloric end of the stomach and pancreas.

The **gastro-epiploica dextra** runs from right to left along the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the **gastro-epiploica sinistra** from the splenic artery. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum.

The **pancreatico-duodenalis superior** descends between the contiguous margins of the duodenum and pancreas. It supplies both these organs, and anastomoses with the inferior **pancreatico-duodenal** branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The **cystic artery** (Fig. 308), usually a branch of the right hepatic, passes upward and forward along the neck of the gall-bladder, and divides into two branches, one of which ramifies on its free surface, the other between it and the substance of the liver.

The **Splenic Artery**, in the adult, is the largest of the three branches of the **cœliac axis**, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side, behind the peritoneum and along the upper border of the pancreas, accompanied by the splenic vein, which lies below it, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the pancreas and great end of the stomach. Its branches are—the

Pancreaticæ Parvæ.

Gastric (*Vasa Brevia*).

Pancreatica Magna.

Gastro-epiploica Sinistra.

The **pancreatic** are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the *pancreatica magna*. These vessels anastomose with the pancreatic branches of the **pancreatico-duodenal** arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The **gastric (*vasa brevia*)** consists of from five to seven small branches, which arise either from the termination of the splenic artery or from its terminal branches, and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach, anastomosing with branches of the **gastric** and **gastro-epiploica sinistra** arteries.

The **gastro-epiploica sinistra**, the largest branch of the splenic, runs from left to right along the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the **gastro-epiploica dextra**. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

The Superior Mesenteric Artery (Fig. 310).

In order to expose this vessel raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse meso-colon and mesentery join: the artery will then be exposed just as it issues from beneath the lower border of the pancreas.

The **Superior Mesenteric Artery** supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cæcum, ascending and transverse colon; it is a vessel of large size, arising from the fore part of the aorta about a quarter of an inch below the **cœliac axis**; being covered at its origin by the splenic vein and pancreas. It passes forward, between the pancreas and transverse portion of the duodenum, crosses in front of this portion of the intestine, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches—viz., ileo-colic. In its course it forms an arch, the convexity of which is directed

forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by the superior mesenteric plexus of nerves. Its branches are—the

Inferior Pancreatico-duodenal.

Vasa Intestini Tenuis.

Colica Media.

Ileo-colic.

Colica Dextra.

FIG. 310.—The superior mesenteric artery and its branches.

The inferior pancreatico-duodenal is given off from the superior mesenteric, or from its first intestinal branch behind the pancreas. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreatico-duodenal artery. It distributes branches to the head of the pancreas and to the transverse and descending portions of the duodenum.

The vasa intestini tenuis arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum. They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with a similar branch on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third, and a fourth, or even fifth, series of arches is constituted, diminishing in size the nearer they approach the

intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the glands and other structures between the layers of the mesentery.

The *ileo-colic artery* is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the inferior division inosculates with the termination of the superior mesenteric artery, forming with it an arch, from the convexity of which branches proceed to supply the termination of the ileum, the cæcum and appendix cæci, and the ileo-cæcal valve. The superior division inosculates with the *colica dextra* and supplies the commencement of the colon.

The *colica dextra* arises from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum to the middle of the ascending colon, divides into two branches—a descending branch, which inosculates with the *ileo-colic*; and the ascending branch, which anastomoses with the *colica media*. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The *colica media* arises from the upper part of the concavity of the superior mesenteric, and, passing forward between the layers of the transverse meso-colon, divides into two branches, the one on the right side inosculating with the *colica dextra*; that on the left side, with the *colica sinistra*, a branch of the inferior mesenteric. From the arches formed by their inosculation branches are distributed to the transverse colon. The branches of this vessel lie between two layers of the transverse meso-colon.

The Inferior Mesenteric Artery (Fig. 311).

In order to expose this vessel draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the front side of the aorta.

The *Inferior Mesenteric Artery* supplies the descending and sigmoid flexure of the colon and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the left side of the aorta, between one and two inches above its division into the common iliacs. It passes downward to the left iliac fossa, and then descends, between the layers of the meso-rectum, into the pelvis, under the name of the *superior hæmorrhoidal artery*. It lies at first in close relation with the left side of the aorta, and then passes as the superior hæmorrhoidal in front of the left common iliac artery. Its branches are—the

Colica Sinistra.

Sigmoid.

Superior Hæmorrhoidal.

The *colica sinistra* passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches—an ascending branch, which inosculates with the *colica media*; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculations branches are distributed to the descending colon.

The *sigmoid artery* runs obliquely downward across the Psoas muscle to the sigmoid flexure of the colon, and divides into branches which supply that part of the intestine, anastomosing above with the *colica sinistra*, and below with the superior hæmorrhoidal artery. This vessel is sometimes replaced by three or four small branches.

The *superior hæmorrhoidal artery*, the continuation of the inferior mesenteric, descends into the pelvis between the layers of the meso-rectum, crossing, in its course, the ureter and left common iliac vessels. It divides into two branches, which descend one on each side of the rectum, and about five inches from the anus break up into several small branches, which pierce the muscular coat of the bowel

and run downward, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coat, to the level of the internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle hæmorrhoidal arteries, branches of the internal iliac, with the inferior hæmorrhoidal branches of the internal pudic.

FIG. 311.—The inferior mesenteric and its branches.

The Suprarenal Arteries (Fig. 307).

The **suprarenal arteries** are two small vessels which arise, one on each side of the aorta, opposite the superior mesenteric artery. They pass obliquely upward and outward, over the crura of the Diaphragm, to the under surface of the suprarenal capsules, to which they are distributed, anastomosing with capsular branches from the phrenic and renal arteries. In the adult these arteries are of small size; in the fœtus they are as large as the renal arteries.

The Renal Arteries (Fig. 307)

The **renal arteries** are two large trunks which arise from the sides of the aorta immediately below the superior mesenteric artery. Each is directed outward across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the

right. Before reaching the hilum of the kidney, each artery divides into four or five branches; the greater number of which generally lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsule, the ureter, and the surrounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta either above or below the renal artery proper, the former being the more common position. Instead of entering the kidney at the hilum, these accessory renal arteries usually pierce the upper or lower part of the gland.

The Spermatic Arteries.

The spermatic arteries are distributed to the testes. They are two slender vessels of considerable length, which arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous, and divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis.

The Ovarian Arteries.

The ovarian arteries (Fig. 313) are the corresponding arteries in the female to the spermatic in the male. They supply the ovaries, are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two layers of the broad ligament of the uterus, to be distributed to the ovary. One or two small branches supply the Fallopian tube; another passes on to the side of the uterus and anastomoses with the uterine arteries. Other offsets are continued along the round ligament through the inguinal canal, to the integument of the labium and groin.

At an early period of foetal life, when the testes or ovaries lie by the side of the spine below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum or pelvis, the arteries become gradually lengthened.

The Phrenic Arteries.

The phrenic arteries are two small vessels which present much variety in their origin. They may arise separately from the front of the aorta, immediately above the cœliac axis, or by a common trunk, which may spring either from the aorta or from the cœliac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon its under surface. The left phrenic passes behind the œsophagus and runs forward on the left side of the œsophageal opening. The right phrenic passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The internal branch runs forward to the front of the thorax, supplying the Diaphragm and anastomosing with its fellow of

the opposite side, and with the musculo-phrenic and comes nervi phrenici, branches of the internal mammary. The external branch passes toward the side of the thorax and inosculates with the intercostal arteries. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava, and the left one some branches to the œsophagus. Each vessel also sends capsular branches to the suprarenal capsule of its own side. The spleen on the left side and the liver on the right also receive a few branches from these vessels.

The Lumbar Arteries.

The **lumbar arteries** are analogous to the intercostal. They are usually four in number on each side, and arise from the back part of the aorta, nearly at right angles with that vessel. They pass outward and backward, around the sides of the body of the lumbar vertebra, behind the sympathetic nerve and the Psoas magnus muscle, those on the right side being covered by the inferior vena cava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebræ each artery divides into a *dorsal* and an *abdominal branch*.

The **dorsal branch** gives off, immediately after its origin, a spinal branch, which enters the spinal canal; it then continues its course backward between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with the similar branches of the adjacent lumbar arteries and with the posterior branches of the intercostal arteries.

The **spinal branch** enters the spinal canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral (see page 521).

The **abdominal branches** pass outward, having a variable relation to the Quadratus lumborum muscle. Most frequently the first branch passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest branch passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary *in front*, the intercostals *above*, and those of the ilio-lumbar and circumflex iliac *below*.

The Middle Sacral Artery.

The **Middle Sacral Artery** is a small vessel, which arises from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body immediately to be described as "Luschka's gland." From it branches arise which run through the meso-rectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the dorsal and lumbar regions.

Coccygeal Gland, or Luschka's Gland.—Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles of each side, and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body about as large as a lentil or a pea, first described by Luschka,¹ and named by him the *coccygeal gland*. Its most obvious connections are with the arteries of the part.

Structure.—It consists of a congeries of small arteries with little aneurismal dilatations derived from the middle sacral and freely communicating with each

¹ *Der Hirnanhang und die Steissdrüse des Menschen*, Berlin, 1860; *Anatomie des Menschen*, Tübingen, 1864, vol. ii. pt. 2, p. 187.

other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabeculæ, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels "consists of the condensed and convoluted metameric dorsal arteries of the caudal segments imbedded in tissue which is possibly a small persisting fragment of the neurenteric canal."

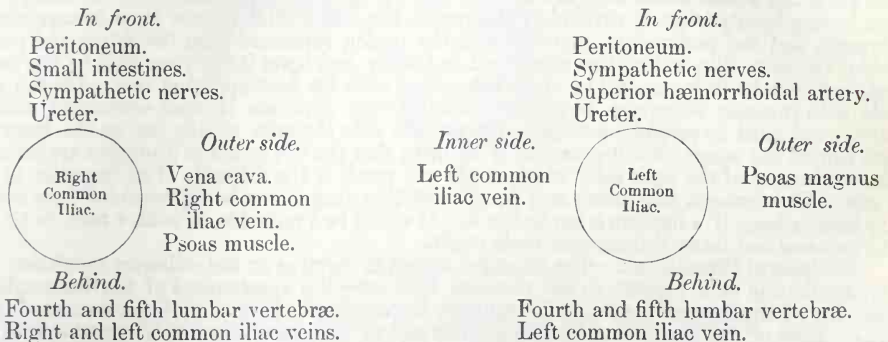

THE COMMON ILIAC ARTERIES.

The abdominal aorta divides into the two **common iliac arteries**. The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downward and outward to the margin of the pelvis, and divide opposite the intervertebral substance, between the last lumbar vertebra and the sacrum, into two branches, the *external* and *internal iliac arteries*, the former supplying the lower extremity; the latter, the viscera and parietes of the pelvis.

The **right common iliac** is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. In front of it are the peritoneum, the small intestines, branches of the sympathetic nerve, and, at its point of division, the ureter. *Behind*, it is separated from the fourth and fifth lumbar vertebræ, with the intervening intervertebral disc, by the two common iliac veins. On its *outer side*, it is in relation with the inferior vena cava and the right common iliac vein, above, and the Psoas magnus muscle below.

The **left common iliac** is in relation, in front, with the peritoneum, branches of the sympathetic nerve, and the superior hæmorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebræ, with the intervening intervertebral disc. The left common iliac vein lies partly on the inner side, and partly beneath the artery; on its outer side, the artery is in relation with the Psoas magnus muscle.

PLAN OF THE RELATIONS OF THE COMMON ILIAC ARTERIES.

Branches.—The common iliac arteries give off small branches to the peritoneum Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar or renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium more frequently below than above.

The **point of division** is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum being above that

point in one case out of eight; and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The *relative length*, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases, the left in fifty-two, whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a zone round the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Surgical Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hæmorrhage implicating the external or internal iliacs. Now that the surgeon no longer dreads opening the peritoneal cavity, there can be no question that the easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened by an incision in either the semilunar line or the linea alba; the intestines are drawn to one side and the peritoneum covering the artery divided. The sheath is then opened, and the needle passed from within outward. On the right side great care must be exercised in passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied the incision in the peritoneum over the artery should be sutured. Formerly there were two different methods by which the common iliac artery was tied, without opening the peritoneal cavity: 1, an anterior or iliac incision, by which the vessel is approached more directly from the front; and 2, a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length according to the amount of fat, is made, commencing just outside the middle of Poupart's ligament and a finger's breadth above it, and carried outward toward the anterior superior iliac spine, then upward toward the ribs, and finally curving inward toward the umbilicus. The abdominal muscles and transversalis fascia are divided, and the peritoneum raised upward and inward until the Psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outward. But if the aneurismal tumor should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar, by making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downward to the ilium; it is then curved forward along the crest of the ilium and a little above it to the anterior superior spine of that bone. The abdominal muscles having been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with its accompanying vein. On the right side both common iliac veins, as well as the inferior vena cava, are in close connection with the artery, and must be carefully avoided. On the left side the vein usually lies on the inner side and behind the artery; but it occasionally happens that the two common iliac veins are joined on the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary hæmorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are—the anastomoses of the hæmorrhoidal branches of the internal iliac with the superior hæmorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

Compression of the Common Iliac Arteries.—The common iliac arteries are most efficiently compressed by Davy's lever. The instrument consists of a gum-elastic tube about two feet long, in which fits a round wooden "lever" considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the Psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried toward the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases

where the meso-rectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side.

Internal Iliac Artery (Fig. 312).

The internal iliac artery supplies the walls and viscera of the pelvis, the generative organs, and inner side of the thigh. It is a short thick vessel, smaller in the adult than the external iliac, and about an inch and a half

FIG. 312.—Arteries of the pelvis.

in length. It arises at the point of bifurcation of the common iliac, and, passing downward to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an *anterior* and *posterior*; from its anterior division a partially obliterated cord, the *hypogastric artery*, extends forward to the bladder.

Relations.—*In front*, with the ureter, which separates it from the peritoneum. *Behind*, with the internal iliac vein, the lumbo-sacral cord, and Piriformis muscle. By its *outer side*, near its origin, with the Psoas magnus muscle.

PLAN OF THE RELATIONS OF THE INTERNAL ILIAC ARTERY.

In the *fœtus* the internal iliac artery (*hypogastric*) is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical opening, the two arteries twine round the umbilical vein, forming with it the umbilical cord, and ultimately ramify in the placenta. The portion of the vessel within the abdomen is called the *hypogastric artery*, and that external to that cavity, the *umbilical artery*.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the *superior vesical artery*.

Peculiarities as regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and *vice versa*.

As regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-sciatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Surgical Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or hæmorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inward from the iliac fossa toward the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound, and by tracing this vessel upward the internal iliac is arrived at, opposite the sacro-iliac articulation. It should be remembered that the vein lies behind and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon its length. It has been seen that in the great majority of the cases examined the artery was short, varying from an inch to an inch and a half; in these cases the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac or upon the external and internal iliacs at their origin.

Probably a better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis of New York on the following grounds: (1) It no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease

in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen's dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied, but the obliteration did not extend to the origin of the external iliac, as the ilio-lumbar artery arose just above this point. Below the point of obliteration the artery resumed its natural diameter, and continued so for half an inch, the obturator, lateral sacral, and gluteal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow's quill, and had a very free anastomosis with the artery of the opposite side and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumor, but on the distal side of the sac it was continued down along the back of the thigh nearly as large in size as the femoral, being pervious about an inch below the sac by receiving an anastomosing vessel from the profunda.¹ The circulation was carried on by the anastomoses of the uterine and ovarian arteries; of the opposite vesical arteries; of the hæmorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the epigastric and internal circumflex; of the circumflex and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.

The **superior vesical** is that part of the foetal hypogastric artery which remains pervious after birth. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the *artery of the vas deferens*. Other branches supply the ureter.

The **middle vesical**, usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculæ seminales.

The **inferior vesical** arises from the anterior division of the internal iliac, frequently in common with the middle hæmorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculæ seminales. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The **middle hæmorrhoidal artery** usually arises together with the preceding vessel. It supplies the anus and parts outside the rectum, anastomosing with the other hæmorrhoidal arteries.

The **uterine artery** (Fig. 313) passes inward from the anterior trunk of the internal iliac to the neck of the uterus. Ascending in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance, anastomosing, near its termination, with a branch from the ovarian artery. It gives off branches to the cervix uteri (*cervical*), and branches which descend on the vagina, and, joining with branches from the vaginal arteries, form a median longitudinal vessel both in front and behind; these descend on the anterior and posterior surfaces of the vagina, and are named the *azygos arteries of the vagina*.

¹ *Medico-Chirurgical Trans.*, vol. xvi.

The **vaginal artery** is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum. It assists in forming the azygos arteries of the vagina.

FIG. 313.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

The **Obturator Artery** usually arises from the anterior trunk of the internal iliac; frequently from the posterior. It passes forward, below the brim of the pelvis, to the upper part of the obturator foramen, and, escaping from the pelvic cavity through a short canal formed by a groove on the under surface of the ascending ramus of the os pubis and the arched border of the obturator membrane, it divides into an internal and external branch. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

Branches.—*Within the pelvis*, the obturator artery gives off an *iliac branch* to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the ilio-lumbar artery; a *vesical branch*, which runs backward to supply the bladder; and a *pubic branch*, which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis, communicating with offsets from the deep epigastric artery and with the corresponding vessel of the opposite side. It is placed on the inner side of the femoral ring. *External to the pelvis*, the obturator artery divides into an *internal* and an *external branch*, which are deeply situated beneath the Obturator externus muscle.

The **internal branch** curves downward along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch and with the internal circumflex artery.

The **external branch** curves round the outer margin of the foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches: one, the smaller, courses inward around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outward in the groove

below the acetabulum, and supplies the muscles attached to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

Peculiarities.—In two out of every three cases the obturator arises from the internal iliac; in one case in three and a half from the epigastric; and in about one in seventy-two cases by two roots from both vessels. It arises in about the same proportion from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 314, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat's ligament (Fig. 314, B), and

FIG. 314.—Variations in origin and course of obturator artery.

under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation was performed.

The **internal pudic** is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **Internal Pudic Artery in the Male** passes downward and outward to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Piriformis and Coccygeus muscles: it then crosses the spine of the ischium and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and gradually approaches the margin of the ramus of the ischium, along which it passes forward and upward, pierces the base of the superficial layer of the triangular ligament of the urethra, and runs forward along the inner margin of the ramus of the os pubis, and divides into its two terminal branches, the *dorsal artery of the penis* and the *artery of the corpus cavernosum*.

Relations.—In the first part of its course, within the pelvis, it lies in front of the Piriformis muscle and sacral plexus of nerves, and the sciatic artery, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium it is covered by the Gluteus maximus and overlapped by the great sacro-sciatic ligament. Here the obturator nerve lies to the inner side and the nerve to the Obturator internus to the outer side of the vessel. In the pelvis it lies on the outer side of the ischio-rectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal (canal of Alcock) formed by the splitting of the obturator fascia. It is accompanied by the pudic veins and the pudic nerve.

Peculiarities.—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the *accessory pudic*, which generally arises from the internal pudic artery

before its exit from the great sacro-sciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and arteria dorsalis penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

Surgical Anatomy.—The relation of the accessory pudic to the prostate gland and urethra is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the lateral operation of lithotomy. The student should also study the position of the internal pudic artery and its branches, when running a normal course with regard to the same operation. The superficial and the transverse perineal arteries are, of necessity, divided in this

FIG. 315.—The internal pudic artery and its branches in the male. (Gegenbaur.)

operation, but the hemorrhage from these vessels is seldom excessive; should a ligature be required, it can readily be applied on account of their superficial position. The artery of the bulb may be divided if the incision be carried too far forward, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outward; but, being bound down by the strong obturator fascia and under cover of the ramus of the ischium, the accident is not very likely to occur unless the vessel runs an anomalous course.

Branches.—The branches of the internal pudic artery are—

Muscular.

Inferior Hæmorrhoidal.

Superficial Perineal.

Transverse Perineal.

Artery of the Bulb.

Artery of the Corpus Cavernosum

Dorsal Artery of the Penis.

The **muscular branches** consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offsets which supply the Levator ani, the Obturator internus, the Piriformis, and the

Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The **inferior hæmorrhoidal** are two or three small arteries which arise from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischio-rectal fossa, they are distributed to the muscles and integument of the anal region.

The **superficial perineal artery** supplies the scrotum and muscles and integument of the perinæum. It arises from the internal pudic in front of the preceding branches, and turns upward, crossing either over or under the Transversus perinæi muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinæ and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perinæum it lies beneath the superficial perineal fascia.

The **transverse perineal** is a small branch which arises either from the internal pudic or from the superficial perineal artery as it crosses the Transversus perinæi muscle. It runs transversely inward along the cutaneous surface of the Transversus perinæi muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the one of the opposite side.

The **artery of the bulb** is a large but very short vessel which arises from the internal pudic between the two layers of the triangular ligament, and, passing nearly transversely inward, between the fibres of the Compressor urethræ muscle, it pierces the bulb of the urethra, in which it ramifies. It gives off a small branch which descends to supply Cowper's gland.

Surgical Anatomy.—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the lateral operation of lithotomy—an accident usually attended in the adult with alarming hemorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perinæum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual and is out of danger in the operation.

The **artery of the corpus cavernosum**, one of the terminal branches of the internal pudic, arises from that vessel while it is situated between the two layers of the triangular ligament; it pierces the superficial layer, and, entering the crus penis obliquely, it runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

The **dorsal artery of the penis** ascends between the crus and pubic symphysis, and, piercing the triangular ligament, passes between the two layers of the suspensory ligament of the penis, and runs forward on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The **Internal Pudic Artery in the Female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **Sciatic Artery** (Fig. 316), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Pyriformis

muscle, and escapes from the pelvis through this foramen between the Piriformis and Coccygeus. It then descends in the interval between the trochanter major and

tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.

Within the pelvis it distributes branches to the Piriformis, Coccygeus, and Levator ani muscles; some hæmorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hæmorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculæ seminales, and prostate gland. *External to the pelvis* it gives off the following branches:

Coccygeal.

Inferior Gluteal.

Comes Nervi Ischiadici.

Muscular.

Anastomotic.

Articular.

The **coccygeal branch** runs inward, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The **inferior gluteal branches**, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The **comes nervi ischiadici** is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

FIG. 316.—The arteries of the gluteal and posterior femoral regions.

The **muscular branches** supply the Gluteus maximus, anastomosing with the gluteal artery in the substance of the muscle: the external rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The **anastomotic artery** is directed downward across the external rotators, and assists in forming the so-called *crucial anastomosis* by anastomosing with the superior perforating and the internal and external circumflex.

The **articular branch**, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The **Ilio-lumbar Artery**, given off from the posterior trunk of the internal iliac, turns upward and outward between the obturator nerve and lumbo-sacral cord, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The **lumbar branch** supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small spinal branch through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the cauda equina.

The **iliac branch** descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The **Lateral Sacral Arteries** (Fig. 312) are usually two in number on each side, superior and inferior.

The **superior**, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, is distributed to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The **inferior** passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the sacra media and opposite lateral sacral arteries. In its course it gives off branches which enter the anterior sacral foramina; these, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **Gluteal Artery** is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short, thick trunk, which passes out of the pelvis above the upper border of the Pyriformis muscle, and immediately divides into a *superficial* and *deep branch*. Within the pelvis it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and, just previous to quitting that cavity, a nutrient artery, which enters the ilium.

The **superficial branch** passes beneath the Gluteus maximus and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The **deep branch** runs between the Gluteus medius and minimus, and subdivides into two. Of these, the superior division, continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The inferior division crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches pierce the Gluteus minimus to supply the hip-joint.

Surface Marking.—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward: the point of emergence of the *gluteal artery* from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the outer part of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the *sciatic and pudic arteries* from the great sciatic notch.

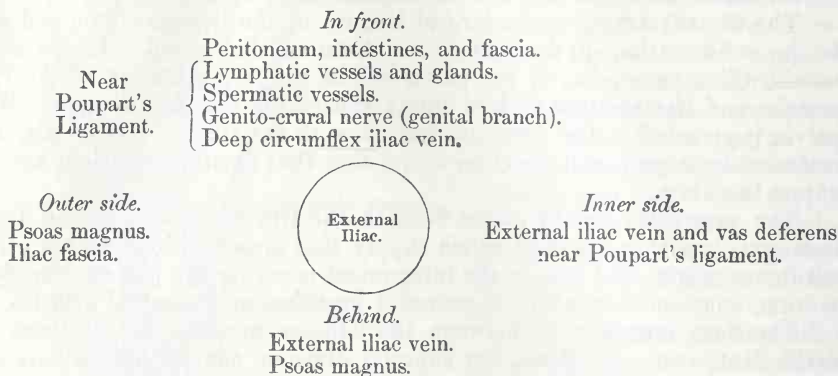

Surgical Anatomy.—Any of these three vessels may require ligating for a wound or for aneurism, which is generally traumatic. The *gluteal* artery is ligated by turning the patient two-thirds over on his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the great trochanter. This must expose the *Gluteus maximus* muscle, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the *Gluteus medius* and *Pyiformis* are now to be separated from each other, and the artery will be exposed emerging from the sciatic notch. In ligation of the *sciatic* artery, the incision should be made parallel with that for ligation of the *gluteal*, but one inch and a half lower down. After the fibres of the *Gluteus maximus* have been separated, the vessel is to be sought for at the lower border of the *Pyiformis*; the great sciatic nerve, which lies just above it, forming the chief guide to the artery.

The External Iliac Artery (Fig. 312).

The **external iliac artery** is larger in the adult than the internal iliac, and passes obliquely downward and outward along the inner border of the *Psoas* muscle, from the bifurcation of the common iliac to *Poupart's* ligament, where it enters the thigh and becomes the femoral artery.

Relations.—*In front*, with the peritoneum, subperitoneal areolar tissue, the termination of the ileum on the right side, and the sigmoid flexure on the left, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is crossed in this situation by the genital branch of the genito-crural nerve and the deep circumflex iliac vein; the vas deferens curves down along its inner side. *Behind*, it is in relation with the external iliac vein, which, at *Poupart's* ligament, lies at its inner side; on the left side the vein is altogether internal to the artery. *Externally*, it rests against the *Psoas* muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near *Poupart's* ligament. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

PLAN OF THE RELATIONS OF THE EXTERNAL ILIAC ARTERY.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 560).

Surgical Anatomy.—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the deep epigastric and circumflex iliac vessels. The patient having been placed in the supine position, an incision should be made, commencing below at a point about three-quarters of an inch above *Poupart's* ligament, and a little external to its middle, and running upward and outward, parallel to *Poupart's* ligament, to a point one inch internal and one inch above the anterior superior spine of the ilium. When the artery is deeply seated, more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance. Another mode of ligating the vessel is the plan advocated by Sir Astley Cooper, by making an incision close to *Poupart's* ligament from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being

made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery, and only the lower end of the vessel can be ligated. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery, and must be cautiously separated from it by the finger-nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligation of the external iliac artery has recently been performed by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision made through the peritoneum at the margin of the pelvis in the course of the artery, and the vessel secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary, the common iliac artery can be ligated instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligated without in any way interfering with the coverings of the sac. Possibly a disadvantage may exist in the greater risk of hernia after this method.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are—the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric, it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb eighteen years after the successful ligature of the external iliac artery by Sir A. Cooper, which is to be found in *Guy's Hospital Reports*, vol. i. p. 50, the anastomosing branches are described in three sets: *An anterior set.*—1, a very large branch from the ilio-lumbar artery to the circumflex iliac; 2, another branch from the ilio-lumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3, two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. *An internal set.*—Branches given off from the obturator, after quitting the pelvis, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. *A posterior set.*—1, three large branches from the gluteal to the external circumflex; 2, several branches from the sciatic around the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymphatic glands, the external iliac gives off two branches of considerable size—the

Deep Epigastric and Deep Circumflex Iliac.

The **Deep Epigastric Artery** arises from the external iliac a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upward, it pierces the transversalis fascia, and, passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches, which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the inferior intercostal arteries (Fig. 301). The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring and beneath the commencement of the spermatic cord. As it passes to the inner side of the internal abdominal ring it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: The *cremasteric*, which accompanies the spermatic cord, and supplies the Cremaster muscle and

other coverings of the cord, anastomosing with the spermatic artery; a *pubic branch*, which runs along Poupart's ligament, and then descends behind the os pubis to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; *muscular branches*, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; others perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the epigastric may take place from any part of the external iliac between Poupart's ligament and two inches and a half above it, or it may arise below this ligament, from the common femoral or from the deep femoral.

Union with Branches.—It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed of two branches, one derived from the external iliac, the other from the internal iliac.

Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament toward the umbilicus; but shortly after this line crosses the *linea semilunaris* the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore *internal* to an oblique inguinal hernia, but *external* to a direct inguinal hernia, as it emerges from the abdomen. It forms the outer boundary of Hesselbach's triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The **Deep Circumflex Iliac Artery** arises from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciæ, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch, which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries.

ARTERIES OF THE LOWER EXTREMITY.

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart's ligament to the lower border of the Popliteus muscle, and here divides into two branches, the anterior and posterior tibial, an arrangement exactly similar to what occurs in the upper limb. For convenience of description, the upper part of the main trunk is named femoral, the lower part, popliteal.

The Femoral Artery (Fig. 317).

The **femoral artery** commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the fore part and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, just on a line with the innermost part of the head of the femur; in the lower part of its course it is in close relation with the inner side of the shaft of the bone, and between these two parts the vessel is some distance from the bone. In the upper third of the thigh it is contained in a triangular space called *Scarpa's triangle*. In the middle third of the thigh it is contained in an aponeurotic canal called *Hunter's canal*.

Scarpa's Triangle.—Scarpa's triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of which is directed downward, and the sides formed externally by the Sartorius, internally by the inner margin of the Adductor longus, and above by Poupart's

ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus (in some cases a small part of the Adductor brevis), and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery giving off in this situation its cutaneous and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the anterior crural nerve dividing into its branches. Besides the vessels and nerves, this space contains some fat and lymphatics.

Hunter's Canal.—This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa's triangle to the femoral opening in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; internally by the Adductors longus and magnus muscles; and covered in by a strong aponeurosis which extends transversely from the Vastus internus across the femoral vessels to the Adductor longus and magnus; lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying at first on the outer side and then in front of the vessels.

For convenience of description, and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the *common femoral artery*, while the remainder of the vessel is termed the *superficial femoral*, to distinguish it from the deep femoral (*profunda femoris*), a large branch given off from the common femoral at its termination, and which, by its derivation from the parent trunk, marks the commencement of the superficial femoral artery.

The *common femoral artery* is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downward of the Transversalis fascia, which forms the anterior part of the sheath of the vessels. It has in front of it filaments from the crural branch of the genito-crural nerve, the superficial circumflex iliac vein, and

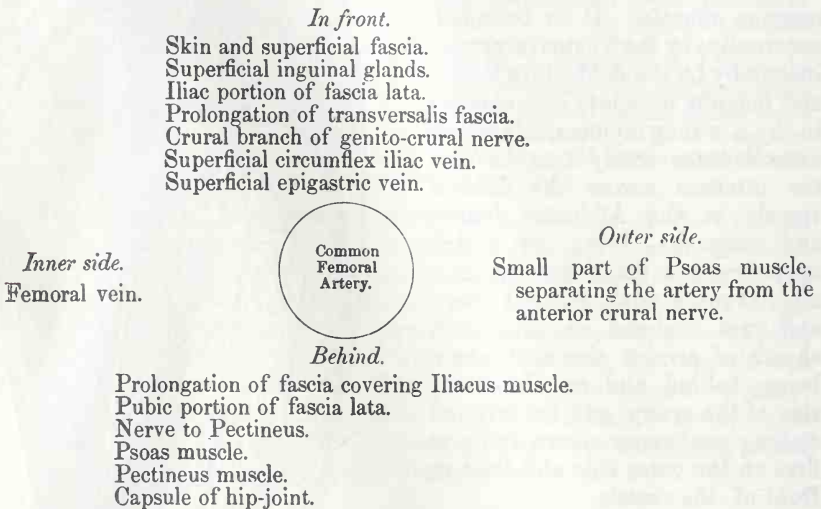

FIG. 317.—The femoral artery.

occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the anterior crural nerve. Separating the artery from the Pectineus muscles in the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle, which forms the posterior layer of the sheath of the vessels. The anterior crural nerve lies about half an inch to the outer side of the common femoral artery, being separated from the artery by a small part of the Psoas muscle. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are enclosed in a strong fibrous sheath formed by the proper sheath of the vessels, strengthened by the fascia lata (see page 419); the artery and vein are separated, however, from one another by a thin fibrous partition.

PLAN OF RELATIONS OF THE COMMON FEMORAL ARTERY.

The **superficial femoral artery** is only superficial where it lies in Scarpa's triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the anterior crural nerve. In Hunter's canal it is more deeply seated, being covered by the integument; the superficial and deep fascia, the Sartorius and aponeurotic covering of Hunter's canal. The internal saphenous nerve crosses the artery from without inward. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus, the Vastus internus muscle, and, at its lower part, the femoral vein. To the inner side is the Adductor longus above and the Adductor magnus and Sartorius below.

PLAN OF RELATIONS OF THE SUPERFICIAL FEMORAL ARTERY.

Behind.

Femoral vein.
 Profunda artery and vein.
 Pectineus muscle.
 Adductor longus.
 Adductor magnus.

The *femoral vein*, at Poupart's ligament, lies close to the inner side of the artery, separated from it by a thin fibrous partition; but lower down it is behind it, and then to its outer side.

The *internal saphenous nerve* is situated on the outer side of the artery, in the middle third of the thigh, beneath the aponeurotic covering of Hunter's canal, but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities.—Double Femoral reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening in the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacro-sciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle, or it may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the prominent tuberosity on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Surgical Anatomy.—*Compression* of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, and also for the cure of popliteal aneurisms, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the ascending ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from within outward, so as to compress the vessel against the inner side of the shaft of the femur.

The **application of a ligature** to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral; and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligation of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz. the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is between four and five inches from its point of origin. In order to expose the artery in this situation, an incision between three and four inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outward. A large vein is frequently met with, passing in the course of the artery to join the internal saphenous vein; this must be avoided, and, the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to expose fully the sheath of

¹ Ligation of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Maunder, *Clin. Soc. Trans.*, vol. ii., p. 37).

the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery in Hunter's canal, an incision should be made through the integument, between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh—i. e., midway between the groin and the knee. The fascia lata having been divided, and the outer border of the Sartorius muscle exposed, it should be drawn inward, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery, the long saphenous nerve on its anterior and outer side.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hæmorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps¹ advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodoform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot-piece.

Collateral Circulation.—When the common femoral is tied the main channels for carrying on the circulation are the anastomoses of the gluteal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the comes nervi ischiadici with the arteries in the ham.

The principal agents in carrying on the collateral circulation after ligature of the superficial femoral artery are, according to Sir A. Cooper, as follows:

"The arteria profunda formed the new channel for the blood." "The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery."

"The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, with arteries passing to the Gastrocnemii, and, lastly, with the origin of the anterior and posterior tibial arteries."

"It appears, then, that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation."²

In Porta's work³ (tab. xii., xiii.) is a good representation of the collateral circulation after the ligature of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper; about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anastomotica magna) and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside through the intervention of the superior external articular artery, with which they both anastomose; and

¹ Heath's *Dictionary of Practical Surgery*, vol. i. p. 525.

² *Med.-Chir. Trans.*, vol. ii. 1811.

³ *Alterazioni patologiche delle Arterie.*

blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular) which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comes nervi ischiadici of the sciatic, which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligature of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death. The whole of the superficial femoral and popliteal artery seems to have been obliterated. The

FIG. 318.—Femoral artery and its branches. (From a preparation in the Museum of the Royal College of Surgeons of England.)

anastomosis by means of the comes nervi ischiadici, which is shown in Porta's plate, is distinctly seen: the external circumflex and the termination of the profunda artery seem to have been the chief channels of anastomoses; but the injection has not been a very successful one.

Branches.—The branches of the femoral artery are—the

Superficial Epigastric.	Profunda	{ External Circumflex. Internal Circumflex. Three Perforating.
Superficial Circumflex Iliac.		
Superficial External Pudic.		
Deep External Pudic.		Muscular.
Anastomotica Magna.		

The **superficial epigastric** arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **superficial circumflex iliac**, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The **superficial external pudic** (superior) arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **deep external pudic** (inferior), more deeply seated than the preceding, passes inward across the Pectineus and Adductor longus muscles, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perinæum; and in the female to the labium, anastomosing with branches of the superficial perineal artery.

The **Profunda Femoris** (*deep femoral artery*) (Fig. 318) nearly equals the size of the superficial femoral. It arises from the outer and back part of the femoral artery, from one to two inches below Poupart's ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the fourth perforating artery), and is distributed to the flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

Relations.—*Behind*, it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front*, it is separated from the superficial femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its *outer side* the origin of the Vastus internus separates it from the femur.

The profunda gives off the following named branches :

External circumflex. Internal circumflex. Four perforating.

The **External Circumflex Artery** supplies the muscles on the front of the thigh. It arises from the outer side of the profunda, passes horizontally outward, between the divisions of the anterior crural nerve and behind the Sartorius and Rectus muscles, and divides into three sets of branches—ascending, transverse, and descending.

The **ascending branches** pass upward, beneath the Tensor fasciæ femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and deep circumflex iliac arteries.

The **descending branches**, three or four in number, pass downward, behind the Rectus, upon the Vasti muscles, to which they are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the anterior crural nerve to the Vastus externus.

The **transverse branch**, the smallest, passes outward over the Crureus, pierces the Vastus externus, and winds round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **Internal Circumflex Artery**, smaller than the external, arises from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis it gives off two branches, one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward and divides into an ascending and a transverse branch (Fig. 257). The *ascending branch* passes obliquely upward upon the tendon of the Obturator externus and under cover of the Quadratus femoris toward the digital fossa, where it anastomoses with twigs from the gluteal and sciatic arteries. The *transverse branch*, larger than the ascending, appears between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries ("the *crucial anastomosis*"). Opposite the hip-joint, the artery gives off an articular vessel, which enters the joint beneath the transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The **perforating arteries** (Fig. 316), usually four in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. They pass backward close to the linea aspera of the femur, under cover of small tendinous arches in the Adductor magnus. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The **first perforating artery** passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces the Adductor magnus close to the linea aspera. It gives off branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscles, and anastomoses with the sciatic, internal and external circumflex, and middle perforating arteries.

The **second perforating artery**, larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh, anastomosing with the first and third perforating. The second artery frequently arises in common with the first. The nutrient artery of the femur is usually given off from this branch.

The **third perforating artery** is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles

of the thigh; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal.

The **fourth perforating artery** is represented by the termination of the profunda femoris artery.

FIG. 319.—Side view of the popliteal artery. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Muscular branches are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus.

The **anastomotica magna** (Fig. 319) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a superficial and deep branch.

The **superficial branch** pierces the aponeurotic covering of Hunter's canal, and

accompanies the long saphenous nerve to the inner side of the thigh. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular.

The **deep branch** descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

Popliteal Artery.

The **popliteal artery** commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle, divides into the *anterior* and *posterior tibial arteries*. A portion of the artery lies in the popliteal space; but above and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

THE POPLITEAL SPACE (Fig. 320).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 255, page 427.

Boundaries.—The **popliteal space**, or the **ham**, is a lozenge-shaped space, widest at the back part of the knee-joint, and deepest above the articular end of the femur. It is bounded externally, above the joint, by the Biceps, and, below the joint, by the Plantaris and external head of the Gastrocnemius. Internally, above the joint, by the Semimembranosus, Semitendinosus, Gracilis, and Sartorius; below the joint, by the inner head of the Gastrocnemius.

Above, it is limited by the apposition of the inner and outer hamstring muscles; below, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.

Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space, lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the upper part of the space, lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial to the artery, to which it is closely united by dense areolar tissue; it is a thick-walled vessel, and lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes the vein is double, the artery lying between the two venæ comites, which are usually connected by short transverse branches. More deeply, and, at its upper part, close to the surface of the bone, is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve. The popliteal lymphatic

glands, four or five in number, are found surrounding the artery; one usually lies superficial to the vessel; another is situated between it and the bone, and the rest are placed on either side of it.

The **Popliteal Artery**, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. *Superficially*, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it above; it then crosses it and lies to its inner side. The internal popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. *Laterally*, the artery is bounded by the muscles which are situated on either side of the popliteal space.

PLAN OF RELATIONS OF POPLITEAL ARTERY.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint. The anterior tibial under these circumstances may pass in front of the Popliteus muscle.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubercle of the tibia.

Surgical Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyper-extension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the femur or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space. The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due no doubt, in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligature of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended

with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course, the patient should be placed in the supine position, with the knee flexed and the thigh rotated outward, so that it rests on its outer surface; an incision three inches in length, beginning at the junction of the middle and lower third of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fasciæ divided. The tendon of the muscle is thus exposed, and is to be drawn forward and the hamstring tendons backward. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the outer side of the artery. The sheath is to be opened and the aneurism needle passed from before backward, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid is the long saphenous vein in the superficial incision. The upper part of the popliteal artery may also be tied by an incision on the back of the limb, along the outer margin of the Semimembranosus, but the operation is a more difficult one, as the internal popliteal nerve and the popliteal vein are first exposed, and great care has to be exercised in separating them from the artery.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

Branches.—The branches of the popliteal artery are—the

Muscular	Superior.	Superior External Articular.
	Inferior or Sural.	Azygos Articular.
Cutaneous.		Inferior Internal Articular.
Superior Internal Articular.		Inferior External Articular.

The **superior muscular branches**, two or three in number, arise from the upper part of the popliteal artery, and are distributed to the lower part of the Adductor magnus and flexor muscles of the thigh, anastomosing with the fourth perforating branch of the profunda.

The **inferior muscular (sural)** are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They arise from the popliteal artery opposite the knee-joint.

The **cutaneous branches** arise separately from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein.

The **superior articular arteries**, two in number, arise one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The *internal branch* winds inward beneath the hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and, passing beneath the tendon of the Adductor magnus, divides into two branches, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. This branch is frequently of small size, a condition which is associated with an increase in the size of the anastomotica magna. The *external branch* passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and deep branch: the superficial branch supplies the Vastus externus, and anastomoses with the descending branch of the external circumflex and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The azygos articular is a small branch arising from the popliteal artery oppo-

FIG. 320.—The popliteal, posterior tibial, and peroneal arteries.

FIG. 321.—Surgical anatomy of the anterior tibial and dorsalis pedis arteries.

site the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The **inferior articular arteries**, two in number, arise from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia below the joint. The *internal* one first descends along the upper margin of the Popliteus muscle, to which it gives branches; it then passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The *external* one passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis.—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and deep plexus. The superficial plexus is situated between the fascia and skin round about the patella; the deep plexus, which forms a close network of vessels, lies on the surface of the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the *anastomotica magna*, the terminal branch of the profunda, the descending branch from the external circumflex, and the anterior recurrent branch of the anterior tibial.

The Anterior Tibial Artery (Fig. 321).

The **anterior tibial artery** commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg: it here lies close to the inner side of the neck of the fibula; it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the *dorsalis pedis*.

Relations.—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins (*venæ comites*), which lie one on each side of the artery; the anterior tibial nerve, coursing round the outer side of the neck of the fibula, comes into relation with the outer side of the artery shortly after it has passed through the opening in the interosseous membrane; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

Tibia.

Anterior ligament of ankle-joint.

Peculiarities in Size.—This vessel may be diminished in size, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

Course.—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Surface Marking.—Draw a line from the inner side of the head of the fibula to midway between the two malleoli. In this line take a point one inch and a quarter below the head of the fibula, and the portion of the line below this point will mark the course of the artery.

Surgical Anatomy.—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision, about four inches in length, should be made through the integument, midway between the spine of the tibia and the outer margin of the fibula, and the deep fascia exposed. The wound must now be carefully dried, its edges retracted, and the white line separating the Tibialis anticus from the Extensor longus digitorum sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anticus separated from adjacent muscles with the handle of the scalpel or a director until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart, the artery will be found lying on the interosseous membrane with the nerve on its outer side or on the top of the artery. The nerve should be drawn outward, and the venæ comites separated from the artery and the needle passed around it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve on the outer side and one of the venæ comites on either side.

The branches of the anterior tibial artery are—the

Posterior Recurrent Tibial.
Superior Fibular.
Anterior Recurrent Tibial.

Muscular.
Internal Malleolar.
External Malleolar.

The **posterior recurrent tibial** is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The **superior fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.

The **anterior recurrent tibial branch** arises from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomos-

ing with the articular branches of the popliteal and with the *anastomotica magna*, assisting in the formation of the *circumpatellar plexus*.

The *muscular branches* are numerous; they are distributed to the muscles which lie on each side of the vessel, some piercing the deep fascia to supply the integument, others passing through the *interosseous membrane*, and anastomosing with branches of the posterior tibial and peroneal arteries.

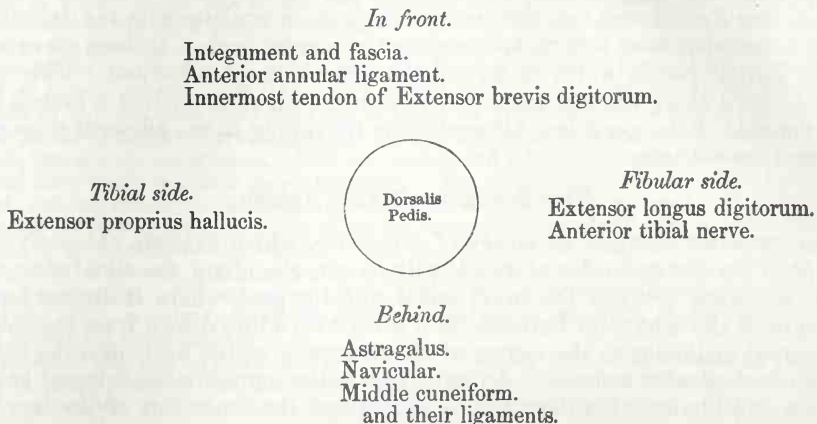

The *malleolar arteries* supply the ankle-joint. The *internal* arises about two inches above the articulation, and passes beneath the tendons of the *Extensor proprius hallucis* and *Tibialis anticus* to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The *external* passes beneath the tendons of the *Extensor longus digitorum* and *Peroneus tertius*, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the *dorsalis pedis*.

The Dorsalis Pedis Artery (Fig. 321).

The *dorsalis pedis*, the continuation of the anterior tibial, passes forward from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the *dorsalis hallucis*, and *communicating*.

Relations.—This vessel, in its course forward, rests upon the *astragalus*, *navicular*, and middle *cuneiform* bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the *Extensor brevis digitorum*. On its *tibial side* is the tendon of the *Extensor proprius hallucis*; on its *fibular side*, the innermost tendon of the *Extensor longus digitorum*, and the termination of the anterior tibial nerve. It is accompanied by two veins.

PLAN OF THE RELATIONS OF THE DORSALIS PEDIS ARTERY.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.

Position.—This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The *dorsalis pedis* artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy.—This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the *Extensor proprius hallucis*, in the interval between it and the inner border of the short *Extensor* muscle. The incision should not extend farther forward than the back part of the first intermetatarsal

space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches.—The branches of the *dorsalis pedis* are—the

Tarsal.

Dorsalis Hallucis.

Metatarsal—Interosseous.

Communicating.

The **tarsal artery** arises from the *dorsalis pedis*, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the *Extensor brevis digitorum*; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **metatarsal** arises a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short *Extensor*, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the *interosseous arteries*, which pass forward upon the three outer *Dorsal interossei* muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes. At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the fore part of each interosseous space they are joined by the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **dorsalis hallucis** (*first dorsal interosseous*) runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the *Extensor proprius hallucis*, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The **communicating artery** dips down into the sole of the foot, between the two heads of the *First dorsal interosseous* muscle, and inosculates with the termination of the external plantar artery, to complete the plantar arch. It here gives off its plantar digital branch, which is named the *arteria magna hallucis*. This artery passes forward along the first interosseous space, and, after sending a branch along the inner side of the great toe, bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery.

The **posterior tibial** is an artery of large size, which extends obliquely downward from the lower border of the *Popliteus* muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the *Abductor hallucis*, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the *internal* and *external plantar arteries*. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the *os calcis*.

Relations.—It lies successively upon the *Tibialis posticus*, the *Flexor longus digitorum*, the tibia, and the back part of the ankle-joint. It is covered by the deep transverse fascia, which separates it above from the *Gastrocnemius* and *Soleus* muscles: at its termination it is covered by the *Abductor hallucis* muscle. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the *tendo Achillis*. It is accompanied by two veins and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

PLAN OF THE RELATIONS OF THE POSTERIOR TIBIAL ARTERY.

Behind the Inner ankle the tendons and blood-vessels are arranged, under cover of the internal annular ligament, in the following order, from within outward: First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side: and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in Size.—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia, and either joins the small tibial artery or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Surgical Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot attended with great hæmorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision, convex backward, should be made through the integument, about two inches and a half in length, midway between the heel and inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venæ comites on each side. The aneurism needle should be passed round the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the venæ comites.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the tendo Achillis. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venæ comites on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inward, so as to avoid wounding the posterior tibial nerve.

The branches of the posterior tibial artery are—the

Peroneal.
Muscular.

Nutrient.
Communicating.

Internal Calcanean.

The **Peroneal Artery** lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the Popliteus muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone, contained in a fibrous canal between the Tibialis posticus and the Flexor longus hallucis, or in the substance of the latter muscle to the lower third of the leg, where it gives off the *anterior peroneal*. It then passes across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the *external calcanean*.

Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is *covered*, in the upper part of its course, by the Soleus and deep transverse fascia; *below*, by the Flexor longus hallucis.

PLAN OF THE RELATIONS OF THE PERONEAL ARTERY.

Peculiarities in Origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

The branches of the peroneal are—the

Muscular.

Communicating.

Nutrient.

Posterior Peroneal.

Anterior Peroneal.

External Calcanean.

Muscular Branches.—The **peroneal artery** in its course gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The *nutrient artery* supplies the fibula.

The *Anterior peroneal* pierces the interosseous membrane, about two inches above the outer malleolus, to reach the fore part of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The *communicating* is given off from the peroneal about an inch from its lower end, and, passing inward, joins the communicating branch of the posterior tibial.

The *Posterior peroneal* passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

The *External calcanean* are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar, and, on the back of the heel, with the internal calcanean arteries.

The *nutrient artery* of the tibia arises from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The muscular branches of the posterior tibial are distributed to the *Soleus* and deep muscles along the back of the leg.

The *communicating branch*, to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the *Flexor longus hallucis*.

The *internal calcanean* are several large arteries which arise from the posterior

FIG. 322.—The plantar arteries. Superficial view.

FIG. 323.—The plantar arteries. Deep view.

tibial just before its division: they are distributed to the fat and integument behind the *tendo Achillis* and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcanean arteries.

The *Internal Plantar Artery* (Figs. 322, 323), much smaller than the external, passes forward along the inner side of the foot. It is at first situated above¹ the *Abductor hallucis*, and then between it and the *Flexor brevis digitorum*, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch. Small superficial digital branches accompany the digital branches of the internal plantar nerve and join the plantar digital arteries of the three inner spaces.

The *External Plantar Artery*, much larger than the internal, passes obliquely outward and forward to the base of the fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second

¹ This refers to the erect position of the body. In the ordinary position for dissection the artery is deeper than the muscle.

metatarsal bones, where it anastomoses with the communicating branch from the *dorsalis pedis* artery, thus completing the *plantar arch*. As this artery passes outward, it is first placed between the *os calcis* and *Abductor hallucis*, and then between the *Flexor brevis digitorum* and *Flexor accessorius*, and as it passes forward to the base of the little toe, it lies more superficially between the *Flexor brevis digitorum* and *Abductor minimi digiti*, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated: it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies upon the *Interossei* muscles opposite the tarsal ends of the metatarsal bones, and is covered by the *Adductor obliquus hallucis*, the flexor tendons of the toes, and the *Lumbricales*.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point; *i. e.* a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

Surgical Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligate it. They must be treated on similar lines to those of wounds of the palmar arches (see page 545). Delorme has shown that it may be ligated from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:

Posterior Perforating.

Digital—Anterior Perforating.

The **Posterior Perforating** are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the *Dorsal interossei* muscles, and anastomose with the interosseous branches from the metatarsal artery.

The **Digital Branches** are four in number, and supply the three outer toes and half the second toe. The *first* passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the *Abductor* and short *Flexor* muscles. The *second*, *third*, and *fourth* run forward along the interosseous spaces, and on arriving at the clefts between the toes divide into collateral branches, which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the fore part of the corresponding interosseous space, a small branch, which inosculates with the interosseous branches of the metatarsal artery. These are the *anterior perforating branches*.

From the arrangement already described of the distribution of the vessels to the toes it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the communicating branch of the *dorsalis pedis*.

THE VEINS.

The Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the *pulmonary* and *systemic*.

The **Pulmonary Veins** are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart.

The **Systemic Veins** are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart.

The **Portal Vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the *vena portæ*. This vessel ramifies in the substance of the liver and breaks up into a minute network of capillaries. These capillaries then re-collect to form the hepatic veins, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the entire capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which only slightly exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form the veins are perfectly cylindrical, like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior. They usually retain, however, the same calibre as long as they receive no branches.

The veins communicate very freely with one another, especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large and very frequent anastomoses. The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

The minute structure of these vessels will be described in the section on General Anatomy.

The systemic veins are subdivided into three sets: superficial, deep, and sinuses.

The **Superficial or Cutaneous Veins** are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called *venæ comites*. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and consist of channels formed by a separation of the two layers of the dura mater, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS.

The *Pulmonary Veins* return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary differ from other veins in several respects: 1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the capillary ramifications of the pulmonary artery, and, uniting together, form one vessel for each lobule. These vessels, uniting successively, form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, forming two trunks on each side, which open separately into the left auricle. Occasionally they remain separate; there are then three veins on the right side. Not unfrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are *in front*, the veins *behind*, and the bronchi *between* the two.

At the root of the lung, the veins are *in front*, the artery *in the middle*, and the bronchus *behind*.

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta and superior vena cava; the left pass in front of the thoracic aorta with the left pulmonary artery.

THE SYSTEMIC VEINS.

The systemic veins may be arranged into three groups: 1. Those of the head and neck, upper extremity, and thorax, which terminate in the superior vena cava. 2. Those of the lower extremity, abdomen, and pelvis, which terminate in the inferior vena cava. 3. The cardiac veins, which open directly into the right auricle of the heart.

VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and interior of the cranium.

Veins of the Exterior of the Head and Face.

The veins of the exterior of the head and face are—the

Frontal.	Temporal.
Supra-orbital.	Internal Maxillary.
Angular.	Temporo-maxillary.
Facial.	Posterior Auricular.
	Occipital.

The **frontal vein** commences on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose by a transverse branch called the *nasal arch*. Occasionally the frontal veins join to form a single trunk, which bifurcates at the

FIG. 324.—Veins of the head and neck.

root of the nose into the two angular veins. At the root of the nose the veins diverge and join the *supra-orbital vein*, at the inner angle of the orbit, to form the *angular vein*.

The **supra-orbital vein** commences on the forehead, communicating with the anterior temporal vein, and runs downward and inward, superficial to the Occipito-frontalis muscle, receiving tributaries from the neighboring structures, and joins the frontal vein at the inner angle of the orbit to form the *angular vein*.

The **angular vein**, formed by the junction of the frontal and supra-orbital veins, runs obliquely downward and outward on the side of the root of the nose, and receives the veins of the ala nasi on its inner side and the superior palpebral veins on its outer side; it moreover communicates with the ophthalmic vein, thus

establishing an important anastomosis between this vessel and the cavernous sinus. Some small veins from the dorsum of the nose terminate in the nasal arch.

The **Facial Vein** commences at the side of the root of the nose, being a direct continuation of the angular vein. It lies behind and follows a less tortuous course than the facial artery. It passes obliquely downward and outward, beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw, with the facial artery, and, passing obliquely outward and backward, beneath the Platysma and cervical fascia, unites with the anterior division of the temporo-maxillary vein, to form a trunk of large size (*common facial vein*), which enters the internal jugular. From near its termination a communicating branch often runs down the anterior border of the Sterno-mastoid to join the lower part of the anterior jugular.

Tributaries.—The facial vein receives, near the angle of the mouth, communicating tributaries of considerable size (the *deep facial* or *anterior internal maxillary vein*) from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek, and the masseteric veins. Below the jaw it receives the submental; the inferior palatine, which returns the blood from the plexus around the tonsil and soft palate; the submaxillary vein, which commences in the submaxillary gland; and, generally, the ranine vein.

Surgical Anatomy.—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by its tributaries, the angular and supra-orbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus, but also by its deep branch, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium (see page 606). These facts have an important bearing upon the surgery of some diseases of the face, for on account of its patency the facial vein favors septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. And on account of its communications with the cerebral sinuses these thrombi are apt to extend upward into them and so induce a false issue.

The **Temporal Vein** commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supra-orbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. This trunk is joined in this situation by a large vein, the *middle temporal*, which receives the blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The temporal vein then descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the temporo-maxillary vein.

Tributaries.—The temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the *transverse facial*, from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the *orbital vein*, which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The **Internal Maxillary Vein** is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, alveolar, some palatine veins, and the inferior dental. These branches form a large plexus, the *pterygoid*, which is placed between the Temporal and External pterygoid and partly between the Pterygoid muscles. This plexus communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesalii, foramen ovale, and foramen lacerum medium, at the base of

the skull. The trunk of the vein then passes backward behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-maxillary vein.

The **Temporo-maxillary Vein**, formed by the union of the temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, an anterior, which passes inward to join the facial vein, and a posterior, which is joined by the posterior auricular vein and becomes the external jugular.

The **Posterior Auricular Vein** commences upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the posterior division of the temporo-maxillary vein, forming the external jugular. This vessel receives the stylo-mastoid vein and some tributaries from the back part of the external ear.

The **Occipital Veins** commence at the back part of the vertex of the skull by a plexus in a similar manner to the other veins. These unite and form one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminate in the internal jugular, occasionally in the external jugular vein. As these veins pass across the mastoid portion of the temporal bone, one of them receives the mastoid vein, which thus establishes a communication with the lateral sinus.

The Veins of the Neck.

The veins of the neck, which return the blood from the head and face, are—the

External Jugular.

Anterior Jugular.

Posterior External Jugular.

Internal Jugular.

Vertebral.
